## EVALUATION

A detailed history often reveals the cause of polyuria. Age at onset, pattern of fluid intake, and rate of onset of polyuria are informative. A thorough feeding history can help identify infants who have water intoxication. New onset of nocturia is often the first manifestation of loss of concentrating ability. Young children with DI can have irritability as a result of hypernatremia and dehydration. Family history is important, given that familial forms of both central and nephrogenic DI exist. In most cases of familial nephrogenic DI, severe polyuria occurs within the first weeks of life. Growth failure is a feature common to both nephrogenic and central DI.

A 24-hour measurement of fluid intake and output is helpful to confirm polyuria before ordering laboratory tests. Urine specific gravity on a first-voided morning specimen is helpful but can be affected by the presence of glycosuria, proteinuria, or radicontrast material. Both types of DI and primary polydipsia result in relatively dilute urine. Patients with disorders resulting in renal tubular damage, such as sickle cell

disease, are more likely to have isosthenuria with specific gravities in the neighborhood of 1.010. Urinalysis with microscopy performed on a first-voided morning specimen also provides valuable information. Protein, casts, or formed blood elements in the urine suggest a renal disorder. Glycosuria with ketonuria strongly suggests DM. Other baseline studies include serum electrolytes, glucose, urea, phosphate, creatinine, calcium, osmolality, liver function tests, and complete blood count (Table 182-2).

Urine osmolality is best interpreted with a concomitant serum sample. A hyperosmolar state would suggest vasopressin deficiency or insensitivity, provided that the serum glucose concentration is normal. Low serum osmolality with hyponatremia suggests either primary polydipsia or water intoxication as the most likely diagnosis. Serum sodium level is usually normal in DI as long as free access to fluids exists and the thirst mechanism is intact. Hypernatremia is commonly seen in infants with DI or when a central lesion exists that also impairs thirst. Blood chemistries will detect causes of nephrogenic DI, such as hypercalcemia and renal impairment.

In polyuric children with low urine specific gravity and no glycosuria, the next step in evaluation is referral to a specialist for a formal water deprivation test to determine whether a defect exists in vasopressin production or renal responsiveness. In the case of patients with very low urine osmolality who are strongly suspected of having nephrogenic DI, the response to exogenous ADH can be determined without the need for prior fluid deprivation. Water deprivation testing should be undertaken with great caution in younger children and should not be performed in newborns. Because of the possibility of volume depletion, the study should be carried out during the day when supervision is optimum and should follow a 24-hour period of free access to fluids.

At baseline, the physician should record vital signs and weight and obtain blood and urine for osmolality, urine specific gravity, serum sodium concentration, serum urea nitrogen level, and hematocrit. Blood should also be obtained at the beginning and conclusion of fluid deprivation to determine plasma ADH levels, which may be helpful if the response to the water deprivation test is equivocal. Fluid intake is restricted for up to 8 hours, during which time the patient must be supervised closely to avoid surreptitious drinking. The patient should be weighed and have vital signs recorded every 2 hours for the first 4 hours, then hourly. Blood and urine should be collected after 4 hours, then every 2 hours for osmolality, serum sodium, and urine specific gravity measurements. The test should be terminated when 1 of the following endpoints is reached: (1) the patient has lost 5% or more of body weight, (2) urine specific gravity is greater than 1.020, (3) urine osmolality exceeds 600 mOsm/kg, (4) plasma osmolality exceeds 300 mOsm/kg, or (5) serum sodium exceeds 147 mEq/L. At the conclusion of the test, weight and vital signs should be recorded and blood and urine collected for osmolality, serum sodium, and urine specific gravity.

In healthy children, and in most children with primary polydipsia, the weight remains constant,

**Table 182-2** Interpretation of Baseline Values

CLINICAL SITUATION	SERUM SODIUM (mEq/L)	SERUM OSMOLALITY (mOsm/kg)	URINE OSMOLALITY	PLASMA VASOPRESSIN
Normal	135–145	280–290	50–1200	Normal
Central diabetes insipidus	Normal or elevated	Normal or elevated	<200	Low
Nephrogenic diabetes insipidus	Normal or elevated	Normal or elevated	<300	Normal or elevated
Primary polydipsia	Low normal	Normal or low	<200	Low

Adapted from Saborio P, Tipton G, Chan J. Diabetes insipidus. *Pediatr Rev.* 2000;21:122–129.

the urine specific gravity rises, and the urine volume decreases. Concentrating ability is frequently impaired in primary polydipsia, resulting in a maximal urine osmolality of 500 to 600 mOsm/kg, compared with greater than 800 mOsm/kg in healthy individuals. This difference likely results from a reduction in the osmotic gradient across the distal renal tubule, with reduced renal sensitivity to vasopressin (Table 182-3).

In the setting of continued diuresis, dehydration, weight loss, and hyperosmolality, the physician should suspect a diagnosis of DI. A small rise in urine osmolality may occur in both forms of DI from either partial vasopressin deficiency (central) or partial vasopressin resistance (nephrogenic). Administration of exogenous ADH may help differentiate between the 2 disorders (see Table 182-3). In an older child, the test can be performed after a water deprivation test or at a subsequent visit. Extreme caution is required when performing this test on infants or small children because of the danger of fluid overload and hyponatremia. The patient is given free access to water after administration of desmopressin acetate (DDAVP), a synthetic derivative of vasopressin. Subsequently, intake, output, and urine specific gravity are recorded every 30 to 60 minutes.

In a patient with complete vasopressin deficiency, the urine output will fall, and urine osmolality will increase significantly. Distinguishing between patients with partial central DI and primary polydipsia may be difficult. Individuals with partial DI may have an exaggerated response to the submaximal rise in vasopressin induced by fluid deprivation. Urine may be maximally concentrated when plasma osmolality is greater than 295 mOsm/kg. In this situation, there may be no further response to administration of exogenous ADH, a pattern suggestive of primary polydipsia. Patients who have primary polydipsia will have an increase in urine osmolality but no response to exogenous ADH because endogenous release is intact. Patients with complete nephrogenic DI do not increase urine osmolality in response to exogenous ADH administration. In patients with partial nephrogenic DI, urine osmolality may increase but will still be significantly lower than 300 mOsm/kg. In contrast, patients with partial vasopressin deficiency typically achieve a urine osmolality greater than 300 mOsm/kg after fluid deprivation.

Patients with vasopressin deficiency are best referred to an endocrinologist or neurologist so that the cause of the DI can be determined. A full investigation of other pituitary functions, visual-field examination, and magnetic resonance imaging of the brain will likely be the next steps in evaluation. Patients should be allowed free access to fluids, and their serum and urine osmolality should be monitored closely. When a diagnosis of central DI has been made, studies must be undertaken to ascertain the cause. Although many cases are idiopathic, a thorough evaluation for an underlying organic lesion must be conducted. The tumor markers human chorionic gonadotropin and  $\alpha$ -fetoprotein should be measured, and magnetic resonance imaging of the pituitary and hypothalamus should be performed to assess for pituitary masses, craniopharyngioma, pinealoma, or pituitary stalk abnormalities. Up to 70% of patients with central DI will lose the normal hyperintense signal of the posterior pituitary.

## MANAGEMENT

Management of polyuria depends largely on the underlying diagnosis and must be individualized carefully. In most cases, the results are gratifying, but patients are often found to have a chronic disease that requires close, long-term surveillance.

In a severely ill patient with central DI, aqueous vasopressin (0.1–0.2 U/kg) may be given subcutaneously every 4 to 6 hours. Vasopressin may also be given by continuous intravenous infusion. Reported starting doses vary from 0.5 to 4.6 mU/kg/hr; these doses should be increased or decreased as needed. Vasopressin is a potent vasoconstrictor and may cause tissue ischemia and severe lactic acidosis, particularly at high infusion rates. Once the child's condition has stabilized, management consists of desmopressin acetate, which can be administered orally in tablet form or instilled intranasally and should be given at the lowest dose that produces antidiuretic effect. When given intranasally, the total daily dose may range from 5 mcg in infants to 40 mcg in older children divided into 2 or 3 doses as needed. Children receiving dose multiples of 10 mcg may use the nasal spray; those receiving smaller or intermediate doses must use the rhinal tube. Desmopressin may also be administered effectively and safely orally. Therapeutic doses of oral desmopressin are generally 15 to 20 times larger than intranasal doses, and greater variability exists in the

**Table 182-3** Interpretation of Water Deprivation Test and Vasopressin Administration

CLINICAL SITUATION	PLASMA VASOPRESSIN	URINE OSMOLALITY	URINE SPECIFIC GRAVITY AFTER VASOPRESSIN
Normal	Increased	>800	Increased
Central diabetes insipidus	Low	<300	Increased
Nephrogenic diabetes insipidus	High	<200	Unchanged
Primary polydipsia	Unchanged	500–600	Unchanged or increased

Adapted from Saborio P, Tipton G, Chan J. Diabetes insipidus. *Pediatr Rev.* 2000;21:122–129.

effective dose. Consequently, response to treatment must be monitored closely if changing route of administration.

Treatment of small children and infants with central DI can be difficult, with rapid changes in serum osmolality potentially leading to complications. The parents must carefully monitor fluid intake and output in the younger child. Because young infants are exclusively fed liquids and have high fluid requirements, the addition of vasopressin can greatly increase the risk for severe hyponatremia. These children are best managed with fluid therapy alone. Small doses of desmopressin may be required if adequate fluid intake is difficult to maintain or if caloric intake is inadequate because of excessive fluid consumption. The risk for hyponatremia can be reduced by allowing escape from the antidiuretic effect for 1 hour before the next dose. A child with adipsia or hypodipsia is best managed by fixing the desmopressin dose and fluid intake. Daily weights and frequent sodium levels are useful in assessing fluid status at home.

In patients who have primary polydipsia, after a neurogenic lesion or gene mutation has been ruled out, medical therapy is not indicated. Psychiatric evaluation, however, may be useful in addressing the origin of the polydipsia.

Patients who have structural renal diseases leading to polyuria should be referred to a pediatric nephrologist. Children with nephrogenic DI should be allowed free access to fluids; parents of infants who have this disorder need to offer frequent water feedings to allow their infants to maintain osmotic homeostasis. A low-salt diet has been helpful in reducing urine output; thiazide diuretics can reduce polyuria further by reducing the amount of urine delivered to the distal tubule. Indomethacin and amiloride, when given concurrently with a thiazide, have each been found effective at reducing urine output.

Osmotic diuresis induced by drugs or diet generally is self-limited. In DM, polyuria secondary to hyperglycemia and glycosuria resolves with treatment of the underlying condition.

### WHEN TO REFER

- Hypotonic polyuria (confirmed by 24-hour urine and urine osmolality <300 mOsm). Perform water deprivation test.
- Polyuria after neurosurgery
- Polyuria and polydipsia secondary to DM

### WHEN TO ADMIT

- Polyuria and dehydration
- Diabetic ketoacidosis
- Severe hyponatremia
- Suspected diabetes insipidus in an infant
- Hyponatremia with MRI or neurologic findings suggestive of a brain tumor

## Chapter 183 PROTEINURIA

Robert P. Woroniecki, MD, MS; Pamela S. Singer, MD

In adults, *proteinuria* is defined as a urinary protein excretion exceeding 150 mg/day. In children, protein excretion exceeding 4 mg/m<sup>2</sup>/hour is considered abnormal. Proteinuria may indicate the presence of renal injury and predict progressive renal disease; in adults, proteinuria is also an established independent risk factor for cardiovascular disease. Large losses of protein through the urine lead to hypercholesterolemia and hypertriglyceridemia, both of which, if sustained for a long time, increase cardiovascular mortality. Medications that reduce proteinuria provide important long-term benefits for adult patients with chronic kidney disease and this beneficial effect has been extrapolated to children.

## PATHOPHYSIOLOGIC FEATURES

Under physiologic conditions, the glomerular filtration barrier, composed of podocytes and vascular endothelium separated by the glomerular basement membrane, limits the passage of macromolecules from blood into urine based on both molecular size and electrical charge. The size barrier for filtration consists of pores with a diameter of approximately 40 Å in the slit diaphragm located between foot processes that is similar or smaller than the size of albumin (69 kDa). In addition, the glomerular capillary wall contains heparan sulfate and proteoglycans, which are negatively charged and thus repel macromolecules with the same electrical charge, such as albumin. Most inflammatory glomerular diseases lead to morphologic alteration of the size barrier and loss of negative charges, leading to proteinuria. Another factor that affects protein movement across glomerular capillary walls is glomerular hemodynamics (ie, glomerular plasma flow rate, hydrostatic and oncotic forces). A reduction in the number of functioning nephrons leads to hyperfiltration in the remaining nephrons and to proteinuria.

Low-molecular-weight proteins, such as  $\beta_2$ -microglobulin, retinol-binding protein, and  $\beta_1$ -microglobulin, are freely filtered through the glomerulus and are subsequently reabsorbed by the proximal tubule. Tubular injury results in impaired ability to reabsorb these proteins and their loss in the urine. Some proteins, such as the Tamm-Horsfall mucoprotein (uromodulin), a major constituent of urinary casts, are formed by the cells of the thick ascending loop of Henle.

## LABORATORY EVALUATION OF PROTEINURIA

The diagnosis of proteinuria depends on laboratory assessment of the level of protein in the urine. The 3 ways urine is tested are the dipstick test, assessment of a timed urine sample, and assessment of the urine protein-creatinine (P/Cr) ratio from an untimed urine sample.

### Dipstick Test

The most commonly performed urine screening method for protein is the dipstick test. Tetrabromophenol on the reagent strip reacts with the amino group of the protein and changes the color of the strip. The test reports findings as negative, trace, and 1+ (30 mg/dL), 2+ (100 mg/dL), 3+ (300 mg/dL), and 4+ (2,000 mg/dL).

The dipstick test primarily detects albumin and is less sensitive to low-molecular-weight proteins and  $\beta$ -globulins. Because the test measures the concentration of protein, false-negative results may occur with highly dilute urine. Conversely, false-positive results may occur with concentrated urine. Generally, a result of 1+ or more in a specimen with a specific gravity of less than 1.015 indicates abnormal protein loss.

The detection of protein depends on pH: extremely alkaline urine may yield a false-positive reading. Other causes of false-positive readings are prolonged immersion of the strip; hematuria, pyuria, or bacteriuria; presence of detergents and contaminating antiseptics, such as chlorhexidine and benzalkonium chloride;

presence of antibiotics, such as penicillins, cephalosporins, sulfonamides, and tolbutamide; or presence of radiographic contrast materials. An alternative office procedure to measure urinary protein is precipitation with sulfosalicylic acid. This measurement is a more accurate estimate of the total urinary proteins, including those of low molecular weight. False-positive results can occur in the previously mentioned conditions.

A positive dipstick result should be confirmed by urinalysis, and urine P/Cr ratio preferably performed on the first urine voided in the morning.

### Timed Urine Sample

The traditional and most accurate way of quantifying urinary protein excretion is to measure protein in a timed sample collected over a 24-hour period. The patient is instructed to void right after waking in the morning. This first urine is discarded, and all subsequent urines are collected. The last urine sample added to the collection should be 24 hours after the first one.

In adults, a protein excretion of less than 150 mg in 24 hours is considered normal. In children, an excretion rate of less than 4 mg/m<sup>2</sup>/hour is considered normal, 4 to 40 mg/m<sup>2</sup>/hour is abnormal, and more than 40 mg/m<sup>2</sup>/hour is considered nephrotic-range proteinuria. The adequacy of the sample can be determined by measuring the creatinine excretion in the sample. Steady-state daily creatinine excretion is 20 mg/kg/day in children from 1 to 12 years of age and 22 to 25 mg/kg in older children, and may be lower in females or children with reduced muscle mass. However, this method is cumbersome, can be impractical in children, and is fraught with error from under- and over-collection.

### Urine Protein-Creatinine Ratio

Measurement of the P/Cr ratio in an untimed (spot) urine sample offers a reliable method for classification of proteinuria. This method is easier than a 24-hour urine collection. Studies in adults and children have shown a strong correlation between untimed urine P/Cr ratio and 24-hour urine collection. A ratio of more than 3.5:1 indicates nephrotic-range proteinuria, and ratios of less than 0.2:1 in patients aged 2 and older and less than 0.5:1 in children aged between 6 and 24 months are considered normal.

## PREVALENCE

Finding proteinuria in a single urine specimen in children and adolescents is relatively common. However, the presence of persistent and not orthostatic proteinuria, also called *fixed proteinuria*, on repeat testing indicates renal disease until proven otherwise. The prevalence of proteinuria, both fixed and orthostatic, is generally between 5% and 15%. Prevalence of orthostatic proteinuria seems to rise with age, peaking in adolescence, with subsequent decline and a nadir in adulthood. For boys, prevalence peaks at age 16 years; for girls, the peak is at 13 years.

## ETIOLOGY

The basic evaluation of proteinuria should address the following issues: pathologic or nonpathological cause; presence or absence of symptoms; amount of protein

loss; presence or absence of associated findings, such as hematuria, hypertension, azotemia; and other urinary or systemic abnormalities.

### Nonpathologic Proteinuria

*Nonpathologic proteinuria* results from the adjustment of the kidney to extraneous physiologic conditions (ie, growth, exercise, fever, systemic illness). The level of proteinuria is generally less than 1 g/day and is not associated with edema.

#### Postural or Orthostatic Proteinuria

*Orthostatic proteinuria* accounts for 60% of all cases of asymptomatic proteinuria in children, with a higher incidence in adolescents. Children with this condition have normal urinary protein excretion in the supine position but spill abnormal amounts of protein in the upright position. The proteinuria decreases to normal range or disappears when they have been recumbent for a few hours, as in overnight sleep. These children are asymptomatic; proteinuria is usually found on a routine urinalysis. The cause of orthostatic proteinuria is unknown. It has been postulated that orthostatic proteinuria might result from higher than normal release of norepinephrine and angiotensin II upon standing, or transient compression of the left renal vein in the fork between the superior mesenteric artery and the aorta (renal nutcracker). Edema, hypertension, and hematuria are absent, and creatinine clearance and complements are normal. Renal ultrasound and histopathologic tests are also normal, although these tests are not usually performed in the evaluation process.

Children with asymptomatic proteinuria should be assessed for postural (orthostatic) proteinuria. The standard method is to collect a first-morning urine and if it is negative for protein on the dipstick, or if the measured P/Cr ratio is less than 0.2:1, the patient has orthostatic proteinuria. The more formal (although not currently used) orthostatic test for postural proteinuria includes 2 separate collections, one in the supine position and the other in the upright position. At bedtime, the child goes to bed immediately after voiding (the urine is discarded). The child is then allowed to sleep. All urine passed during the night, including the first specimen voided the next morning, is collected in a jar (specimen 1), and the time of the first-morning voiding is recorded. Then the child goes about daily activities but collects all urine in a second jar (specimen 2) for approximately the next 12 hours. This collection is the upright collection, which ends at bedtime, when the time is again recorded. In patients with orthostatic proteinuria, the sample obtained in the supine position will be free of protein or will contain a normal amount of protein; however, the sample obtained in upright position will contain an abnormal amount of protein. Children with orthostatic proteinuria generally excrete less than 1 g of protein in 24 hours.

The diagnosis of postural proteinuria can also be made by assessing the first-morning urine. If this sample has no protein, or if it has a P/Cr ratio less than 0.2:1, then a presumptive diagnosis of orthostatic

proteinuria can be made. Long-term follow-up studies in adults have documented the benign nature of orthostatic proteinuria, although rare cases of glomerulosclerosis have been identified later in life in patients who were initially found to have proteinuria with an orthostatic component. Therefore, long-term follow-up of children is necessary unless the proteinuria resolves. Signs to anticipate include appearance of hematuria, hypertension, increase in serum creatinine concentration, or proteinuria exceeding 1 g/day.

#### Transient Proteinuria

As many as 30% to 50% of children with proteinuria may have *transient, nonfixed proteinuria*. It can accompany fever, exercise, stress, dehydration, congestive heart failure, or seizures. Transient proteinuria may be found in children having a temperature of 38.3°C or higher. It usually does not exceed 2+ on the dipstick test and resolves when the fever abates.

Proteinuria associated with vigorous exercise rarely exceeds 2+ on the dipstick test. Transient proteinuria seems to be related to intensity of exercise rather than duration. It may be explained by an increased glomerular filtration barrier permeability and a partial inhibition of tubular reabsorption of protein. The effect of exercise increases with age. Transient proteinuria is considered benign if proteinuria resolves after 48 hours of rest.

### Pathologic Proteinuria

#### Persistent or Fixed Asymptomatic Proteinuria

Patients with a positive dipstick test (1+ or greater) should undergo a more accurate test, such as P/Cr ratio or a quantitative measurement of protein excretion. Orthostatic proteinuria should be excluded by repeat measurements on a first-morning void if the initial sample was taken at random. In the absence of other abnormalities, patients with 2 or more positive semiquantitative or quantitative tests, 1 to 2 weeks apart, are diagnosed as having fixed proteinuria. The prevalence in school-aged children may be as high as 6%. Various causes are listed in Table 183-1.

*Pathologic proteinuria* can be classified as either glomerular or tubular. Glomerular proteinuria, which is the more common of the 2 forms, is associated with increased permeability of glomerular filtration barrier. Glomerular proteinuria may be selective (plasma proteins with molecular weights up to and including albumin), as in minimal change disease, or nonselective (albumin and large-molecular-weight proteins, such as immunoglobulin G), as in most forms of glomerulonephritis. *Tubular proteinuria* results from decreased tubular protein reabsorption that results from tubular dysfunction (see Table 183-1).

#### Symptomatic Proteinuria

Symptomatic proteinuria associated with gravity-dependent edema, hypoalbuminemia, and hyperlipidemia is defined as a nephrotic syndrome. However, some children with nephrotic-range proteinuria and hypoalbuminemia remain completely asymptomatic. Edema in nephrotic syndrome results from multiple factors acting in concert, including increased distal nephron sodium reabsorption, increased capillary

**Table 183-1**      **Classification of Pathologic Proteinuria**

<b>GLOMERULAR</b>	<b>TUBULAR</b>
<b>NEPHROTIC SYNDROME</b> Idiopathic Minimal change Mesangial proliferation Focal segmental glomerulosclerosis Membranous nephropathy  <b>GLOMERULONEPHRITIS</b> Postinfectious Immunoglobulin A nephropathy Membranoproliferative glomerulonephritis <b>SYSTEMIC DISEASE</b> <b>SYSTEMIC LUPUS ERYTHEMATOSUS</b> <b>VASCULITIS</b> <b>TUMOR</b> <b>SUBACUTE BACTERIAL ENDOCARDITIS</b> <b>INFECTION (HIV, HEPATITIS)</b> <b>DRUGS OR TOXINS</b> <b>OBESITY</b> <b>OTHER</b>	<b>GENETIC</b> Polycystic kidney disease Cystinosis Wilson disease Lowe syndrome Galactosemia Renal tubular acidosis Dent disease  <b>ACQUIRED</b> Interstitial nephritis Acute tubular necrosis Heavy metal poisoning Drugs or toxins

permeability, and low plasma oncotic pressure associated with hypoalbuminemic states.

Proteinuria may be associated with other abnormalities, including hematuria, hypertension, and azotemia, as seen in glomerulonephritis. Patients with a combination of nephritis and nephrotic syndrome pose a clinical challenge even to the most experienced nephrologist.

## EVALUATION

### History

The first step in evaluating a child with proteinuria is obtaining a thorough history. History should include questions about recent illnesses, fever, rash, and arthralgias; change in urine output and color; symptoms of chronic disease (eg, weight loss, fatigue); and duration and severity of symptoms. History of urinary tract infections and family history of urinary reflux, hypertension, and deafness are important.

### Physical Examination

Physical examination should include measurements of growth parameters, blood pressure, and identification of edema, ascites, and pallor, as well as documentation of the presence or absence of any joint or skin lesions.

### Laboratory Evaluation

The presence of proteinuria should be confirmed by a urine P/Cr ratio on a first-morning urine sample. Once confirmed, fixed proteinuria should be quantified by a 24-hour urine collection for measurement of protein and creatinine (to determine adequacy of the sample). Serum electrolytes, blood urea nitrogen, and creatinine help determine the level of kidney function. Serum albumin, cholesterol, and triglycerides guide

the determination of the severity of metabolic changes that occur as a result of urine protein loss. Complement levels, anti-streptolysin O titers, hepatitis serologic testing, and HIV testing may be indicated based on the child's history. Renal ultrasound may be performed to assess for structural abnormalities. The patient should be referred to a pediatric nephrologist if any abnormalities are found during the initial workup. Some of the other warning signs of proteinuria are listed in Box 183-1.

The steps in evaluating proteinuria are illustrated in Figure 183-1.

Asymptomatic children with proteinuria should be tested to determine its etiology.

Assessment of total protein is appropriate in children to identify both albuminuria and low-molecular-weight proteinuria. Patients with a positive dipstick test of 1+ or greater should undergo confirmation by assessment of the P/Cr ratio within 3 months. Under most circumstances, first-morning spot urine protein and creatinine samples should be used to detect and monitor proteinuria in children.

Orthostatic proteinuria must be excluded by measuring P/Cr ratio in a first-morning urine sample. Patients with 2 or more positive first-morning P/Cr tests, obtained at 1- to 2-week intervals, should be diagnosed as having persistent or fixed proteinuria. Monitoring proteinuria in patients with chronic kidney disease should be performed by quantitative methods.

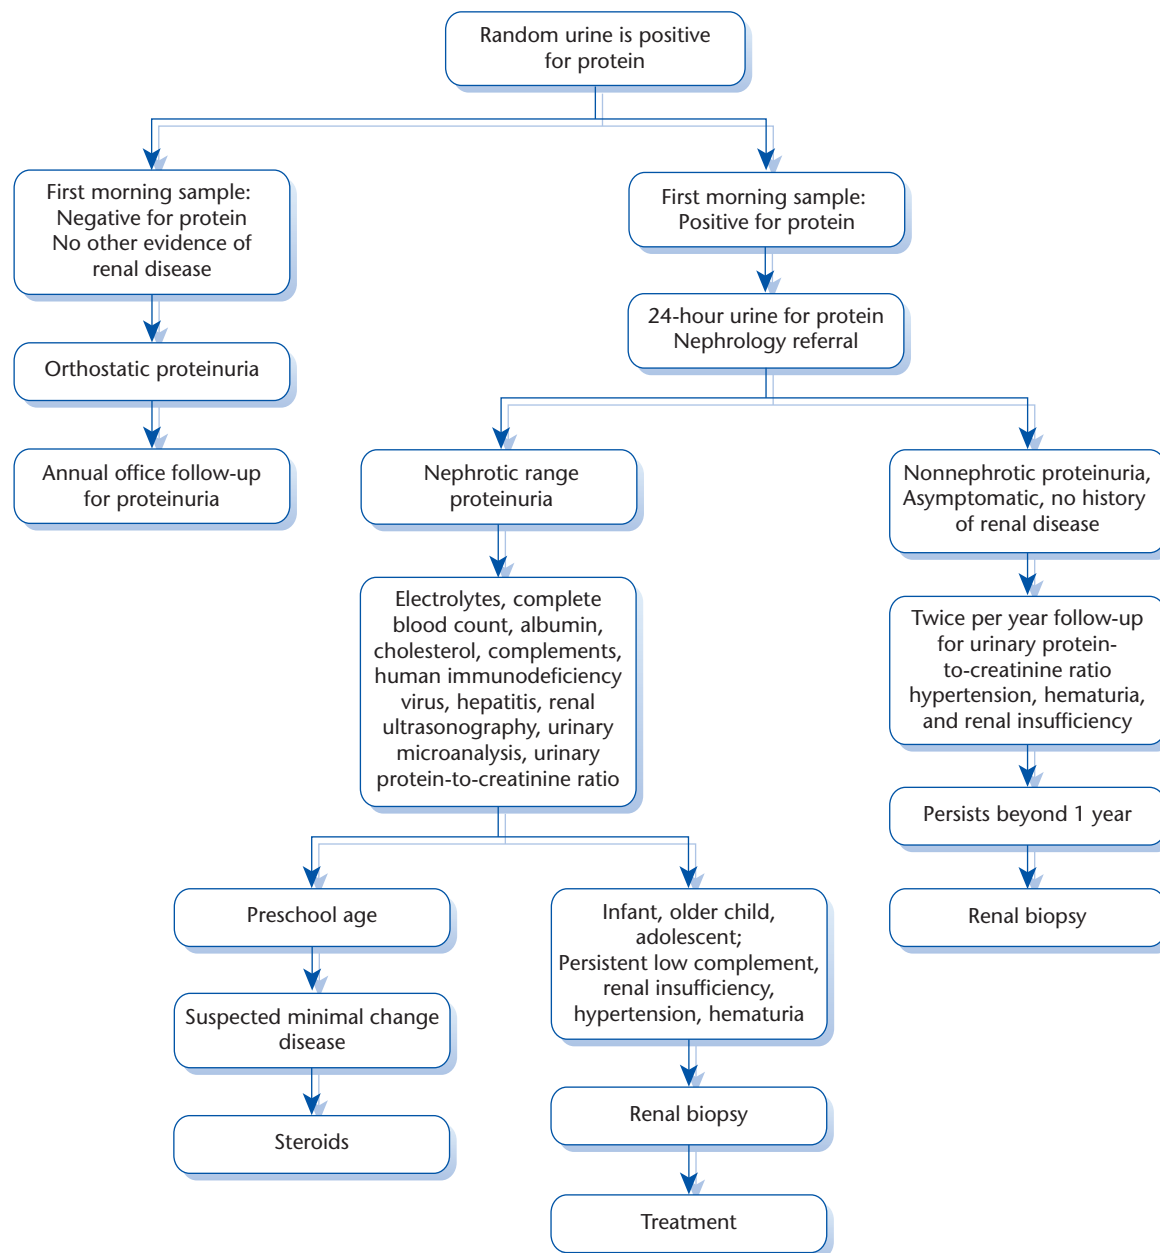

## MANAGEMENT

If orthostatic proteinuria is diagnosed, the child should be monitored with annual office visits and check of first-morning urine P/Cr ratio. Renal biopsy should be considered in certain situations with persistent proteinuria (see Box 183-2).

**BOX 183-1 Warning Signs of Proteinuria**

- Persistent, fixed, nonorthostatic proteinuria
- Proteinuria associated with other urinary abnormalities, such as hematuria, or urinary casts
- Proteinuria associated with renal insufficiency, anemia, or hypertension
- Family history of renal disease, kidney stones, dialysis, deafness, or autoimmune conditions
- Proteinuria associated with comorbidities such as prematurity, congenital anomalies of other organ systems, hypertension, diabetes, and obesity

**Figure 183-1** Diagnostic approach in a patient with proteinuria.

**BOX 183-2 Indications for Renal Biopsy in Persistent Proteinuria**

- Fixed, asymptomatic, isolated proteinuria >1 g/day
- Persistent hematuria and cellular casts
- Renal insufficiency
- Persistently low complement levels
- Hypertension
- Systemic symptoms such as recurrent rashes, joint pains, or fever
- Systemic lupus erythematosus
- Family history of kidney disease or autoimmune disease
- Corticosteroid-resistant nephrotic syndrome

If isolated fixed proteinuria less than 1 g/day is detected (urine P/Cr ratio), restrictions on the child's lifestyle and physical activity are not necessary. Children with proteinuria should receive the recommended daily allowance of protein for their age.

**WHEN TO REFER**

- Persistent, fixed, nonorthostatic proteinuria
- Proteinuria associated with other urinary abnormalities, such as hematuria
- Proteinuria associated with renal insufficiency, anemia, or hypertension
- Family history of renal disease, deafness, or autoimmune condition
- Proteinuria associated with comorbidities such as prematurity, congenital anomalies of other organ systems, hypertension, diabetes, and obesity

**WHEN TO ADMIT**

- Anasarca resistant to outpatient management
- Proteinuria associated with significant renal insufficiency
- Proteinuria associated with significant hypertension

**Chapter 184  
PRURITUS**

Nancy K. Barnett, MD

Pruritus, or itch, is the subjective perception of a cutaneous disturbance that is relieved by scratching or rubbing. It is usually not brought to the primary care physician's attention unless it is generalized, chronic, or associated with an eruption. In such instances, however, pruritus must be treated with great respect because severe itching can be incapacitating. In addition, scratching or rubbing the itch can produce extensive disfigurement in the form of linear excoriations or lichenified plaques and can predispose the patient to cutaneous infections. Constant scratching can even cause social isolation because, at times, people view the child with pruritus as being contagious or unclean.

**DEFINITION OF TERMS**

Because itch is a subjective sensation, objective evaluation to delineate its pathophysiologic characteristics has been difficult. However, current thinking implicates nonspecific itch receptors. Thought to be free, fine nerve endings at the dermoepidermal junction, these receptors transmit the pruritic sensation along dedicated, slow-conduction velocity, unmyelinated C fibers. The exact mediators and their release triggers are unknown. Mast cell histamine has elicited itch fairly consistently in experimental settings and appears to be active in human disease, as may be other local mediators such as substance P and interleukin. Other experimental triggers that have produced itch are physical pressure, heat, and electric shock. Researchers believe that the nerve impulses from the intraepithelial histamine-sensitive, unmyelinated C fibers ascend to the lamina I in the dorsal

horn of the spinal cord and travel along the contralateral spinothalamic tract to the thalamus. They are then transferred to multiple areas of the cortex and are interpreted as itch. A subsequent desire to scratch arises in the cortex. The dorsolateral prefrontal cortex and contralateral caudate nucleus and putamen areas in atopic patients and the anterior cingulate cortex have been identified as activated when histamine-induced itch and scratch are traced. In contrast, the primary motor and sensorimotor cortices and superior parietal lobe are activated in healthy controls. Itch is not a mild form of pain; the pathways are different, and aspirin alone does not relieve itch.

Certain circumstances alter the interpretation of the degree of pruritus. For example, the itch threshold in and around areas of active dermatitis can be lowered by psychic stress, decreased skin hydration, or increased skin temperature, and during the night. Pain can inhibit the itch sensation, and scratching can stimulate pain receptors.

## DIFFERENTIAL DIAGNOSIS

In children, local cutaneous disease rather than systemic disease is by far the most common cause of generalized pruritus. Pruritogenic itch arising in the skin is the focus of this chapter, and discussing neuropathic, neurogenic, and psychogenic itch is beyond the scope. The major differential diagnoses of generalized pruritus with skin lesions in children are infestation (scabies, pediculosis, insect bites, and papular urticaria), atopic dermatitis, miliaria, contact dermatitis, and acute or chronic urticaria.

Children may also itch with cutaneous diseases such as psoriasis, lichen planus, and linear immunoglobulin A bullous disease of childhood. These children should be referred to a dermatologist for evaluation and management, as should a child with pruritus who is otherwise healthy and does not have bites, eczema, heat rash, contact dermatitis, or hives. The child who has pruritus, from whatever cause, is at risk for psychological damage, infection secondary to impetiginization, and scarification.

Systemic causes of itch in the child who has pruritus but no skin lesions are hyperthyroidism and hypothyroidism, leukemia or lymphoma, chronic renal failure, obstructive biliary disease, and xerosis (generalized dry skin).

## EVALUATION AND MANAGEMENT

Most of the common cutaneous diseases associated with generalized pruritus can be diagnosed based on a thorough history and physical examination. The answers to the following questions may help diagnose infestation of one sort or another and direct therapy toward topical steroids, long clothes, and repellents:

Are any individual pruritic papules found with a central punctum?

If so, are they on exposed or nonexposed areas?

Does anyone else in the family have similar lesions? A family history of allergy, asthma, or eczema

in a child who has a chronic eczematous dermatitis over extensor surfaces in infancy and flexural areas in childhood suggests atopic dermatitis. Hydration and emollients will reduce the pruritus and should be the mainstay of therapy, although mid- and low-potency topical steroids for inflammation, antibiotics for secondary infection, and cool compresses may also be required to bring the scratch-itch cycle under control. Short courses (<8 weeks) of topical immunomodulators such as tacrolimus and pimecrolimus may be helpful in relieving atopic itch on facial skin and thin areas such as the axillae, but these medications should not be prescribed as chronic therapy. A tolerable (nonsoporific) dose of an antihistamine may relieve itch and should be given about 1 hour before bedtime because the itch threshold is lower at night than it is during the daytime. Hydroxyzine seems to be the most effective agent. Data conflict about the use of nonsedating antihistamines for controlling itch. Pinpoint crystalline or erythematous papules in areas of occlusion and sweating—that is, miliaria crystallina and miliaria rubra (heat rash)—can be controlled by simple measures such as applying dusting powders, avoiding tight clothing, and reducing exposure to high ambient temperatures.

In most instances, contact dermatitis is readily recognizable because of a linear array of papulovesicular erythematous lesions and sharp borders that conform to the shape of the contactant.

Acute urticaria, usually from exposure to a drug or other ingestant, produces intensely pruritic, erythematous, and edematous plaques and papules. Thorough historical and environmental sleuthing may reveal the cause of a contact allergic or contact irritant dermatitis, but the cause of 90% of acute urticaria cases remains a mystery. If the patient has not used any new drug or food, and if the hives persist despite regular use of antihistamines for several days, then a reasonable course of action would be to obtain a throat culture and a complete blood count with differential and to screen for mycoplasmal disease and infectious mononucleosis to rule out occult streptococcal, mycoplasmal, and viral infections. On rare occasions, a skin biopsy may be helpful. Physical urticarias should demonstrate dermatographism, which can be a helpful diagnostic tool.

For the child who has pruritus with no primary skin disorder, a complete blood count with differential count, complete chemistry panel, thyroid function tests (thyroid-stimulating hormone/free T<sub>4</sub>), urinalysis, and chest radiograph should be obtained to assess for possible systemic causes, especially before suggesting a psychogenic cause for the itching.

To relieve itching and prevent scarring (both mental and physical), the scratch-itch cycle must be broken. Itching provokes scratching, and when the scratching stops, the itching returns. To control itching, the following steps can be helpful:

- Keep the patient's fingernails short to prevent damage from scratching.
- Keep the child fully clothed except when applying medications.

- Apply bland emollient creams frequently, especially after bathing. Overwashing, especially without sealing in the water with an occlusive cream, may dry out the skin and worsen itch. A home humidifier may increase the relative humidity in the air and lessen dry skin itch.
- Apply cool compresses to relieve intense pruritus and to remove crusts and debris.
- Apply topical steroids for short periods (generally <2 weeks) to control inflammation.
- Increase the dose of antihistamine until the scratching stops or marked drowsiness occurs, and then reduce the dose to a level that controls the scratching but does not cause drowsiness.
- Advise the family to avoid stress, heat, and irritants (eg, wool, pet danders).
- See the patient frequently to provide support.
- If the child is old enough to understand, explain why these methods are being used.

Topical capsaicin, menthol, phenol, doxepin, and pramoxine may be indicated for localized use in some cases, but the potential for contact irritation and systemic absorption limits their prolonged or widespread use. Referral to the dermatologist is generally indicated in such a circumstance. Ultraviolet B light therapy may be helpful for generalized pruritus such as occurs in biliary cirrhosis or severe chronic atopic dermatitis. Chronic localized and intractable itch may respond to neurologic “sensor resetting,” in which the brain is fooled into believing the affected area is normal by mirror treatment, because we have come to understand that the sensation of itch results more from central perception than local reception.

### WHEN TO REFER

- Pruritus with uncommon disease (eg, psoriasis, bullae)
- Chronic pruritus without cutaneous disease to evaluate for systemic cause
- Pruritus uncontrolled by usual topical steroids and antihistamines

### Chapter 185

## PUBERTY: NORMAL AND ABNORMAL

Robert K. Kritzler, MD; Dominique Long, MD;  
Leslie Plotnick, MD

Disorders of pubertal development constitute one of the most frequent referrals to pediatric endocrinology clinics. In many cases, no endocrine problem is found. A referral may be avoided by a careful evaluation, including family history, and a few simple laboratory procedures. The availability of pediatric endocrinology consultation and the pediatrician or other physician's level of comfort in diagnosing and treating disorders of puberty heavily influence the decision to refer.

### NORMAL PUBERTY

During puberty, a series of complex hormonal changes takes place. The hypothalamus secretes pulses of gonadotropin-releasing hormone (GnRH), which stimulates pituitary gonadotropin production of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Concomitantly, the previously very sensitive hypothalamic-pituitary-gonadal feedback loop becomes less sensitive to the negative effect of gonadal steroids. As a result, gonadotropin levels rise, stimulating the secretion of greater amounts of sex steroids, either testosterone or estradiol, depending on the gender of the child, leading to the physical changes of puberty. This process is called *gonadarche*. The hypothalamic-pituitary-gonadal axis is active during fetal life and infancy until it enters an inactive state during the prepubertal years. Genetic factors determine 50% to 80% of the variation in pubertal timing. Environmental influences also play a role, particularly nutritional status. It has also been suggested that environmental chemicals capable of disrupting endocrine activity may affect pubertal timing. Leptin, which is secreted by adipocytes and regulates appetite and metabolism through the hypothalamus, is thought to play a permissive role in regulating the timing of puberty. Adrenarche is a separate process that refers to an increase in the secretion of adrenal androgens during puberty and is associated with the development of pubic hair, axillary hair, body odor, and acne. The mechanism that triggers the maturation of the adrenal cortex at puberty remains poorly understood.

In most girls, puberty begins between 8 and 13 years of age, with breast development (thelarche) usually the first sign. Menarche follows the onset of breast development by approximately 2 years. A growth spurt accompanies the changes, usually peaking before menarche. The range of normal variation, however, is quite wide, and differences have been reported between ethnic groups. A secular trend toward earlier puberty has taken place: the most recent data from the National Health and Nutrition Examination Survey (NHANES) 1992–2002 show a decline in the overall average age at menarche to 12.34 years (12.06 years, 12.52 years, and 12.09 years in non-Hispanic black

girls, non-Hispanic white girls, and Mexican American girls, respectively). Although an association exists between earlier sexual maturation in girls and increasing levels of adiposity, it remains unclear from existing data whether this relationship is causal. The average age at menarche declined by 2.3 months between NHANES III (1988–1994) and NHANES 1999–2002. Significantly, NHANES 1999–2002 had more girls with body mass index greater than the 85th or 95th percentile and had a different racial and ethnic composition. Although the overall age at menarche decreased, the changes within racial and ethnic groups was much smaller, indicating that the overall decrease in age at menarche may be because of changes in the population distribution of race and ethnicity and relative weight.

The mean ages for onset of breast development according to NHANES III data were 10.25, 11.05, and 10.70 years in non-Hispanic black girls, non-Hispanic white girls, and Mexican American girls, respectively. Similarly, the mean ages for onset of sexual hair in girls were 10.25, 10.96, and 11.17 years. A recent multicenter study suggests that there continues to be a modest decrease in mean age of breast development, especially in black and Hispanic girls.

In most boys, puberty begins between 9 and 14 years of age. Testicular enlargement is usually the first sign of puberty. NHANES III data found the mean ages of genital development in boys to be 10.79, 11.08, and 11.09 years for non-Hispanic black boys, non-Hispanic white boys, and Mexican American boys, respectively. Similarly, the mean ages for onset of sexual hair were 11.48, 11.81, and 12.20 years. Peak height velocity for boys is typically 2 years later than it is for girls and usually occurs during mid to late puberty (see Table 185-1 for summary of pubertal milestones by age).

The time of puberty is one of profound change, both physical and psychological. Problems of sexual identity, body image, adolescent independence, and peer acceptance are frequent. Because the ranges of age of normal puberty are wide, children of similar chronologic age may have markedly different physical maturity. When pubertal development is precocious or delayed, many of these problems are compounded.

## GYNECOMASTIA

Pubertal gynecomastia occurs in approximately 40% of healthy boys and usually resolves within 2 years. Clinical presentation may include breast tenderness and asymmetry. The mean age of occurrence is between 14 and 15.5 years and usually occurs after Tanner stage 3. Pubertal gynecomastia is thought to result from an increase in the ratio of estrogen to androgen. Treatment in most cases is reassurance; however, gynecomastia that does not resolve after 2 years or that develops rapidly may require a referral. Initial screening blood work includes levels of testosterone, estradiol, LH, FSH, prolactin, and a  $\beta$ -human chorionic gonadotropin as well as liver function tests. Medical therapy with clomiphene (antiestrogen), tamoxifen (estrogen antagonist), testolactone (peripheral aromatase inhibitor), and danazol (synthetic derivative of testosterone) has been reported to be successful; however, no randomized controlled trials have been conducted. Surgical intervention remains the mainstay of treatment. Whereas most pubertal gynecomastia is benign, pathologic causes include Klinefelter syndrome, partial androgen insensitivity syndrome, hyperprolactinemia, liver disorders, adrenal carcinoma, biosynthetic defects in testosterone production, androgen receptor defects, increased activity of peripheral aromatase, and certain drugs. Drugs that have an estrogen-like effect (diethylstilbestrol, oral contraceptive pills, digitalis, estrogen-containing cosmetics), that increase estrogen formation (gonadotropins, clomiphene), or that inhibit testosterone action (ketoconazole, spironolactone, cimetidine, isoniazid, methyldopa, captopril, tricyclic antidepressants, diazepam, marijuana, phenothiazines) have been associated with gynecomastia.

## DELAYED PUBERTY

Few matters are of greater concern to the adolescent than remaining short in stature or sexually underdeveloped. Delayed development demands the immediate attention of the physician.

Puberty is considered delayed in girls who have no breast development by 13 years of age or in boys who have no testicular enlargement by 14 years of age. In

**Table 185-1** Onset of Pubertal Milestones (Years)<sup>a,b</sup>

	NON-HISPANIC WHITES	NON-HISPANIC BLACKS	MEXICAN AMERICANS
<b>GIRLS</b>			
Thelarche	11.05 (9.7) <sup>c</sup>	10.25 (8.8) <sup>c</sup>	10.7 (9.3) <sup>c</sup>
Sexual hair development	10.96	10.25	11.17
Menarche	12.52	12.06	12.09
<b>BOYS</b>			
Testicular enlargement	11.08	10.79	11.09
Sexual hair development	11.81	11.48	12.20

<sup>a</sup>Note: All ages are expressed as means.

<sup>b</sup>From National Health and Nutrition Examination Survey III (1988–1994) and National Health and Nutrition Examination Survey (1999–2002).

<sup>c</sup>Biro FM, Greenspan LC, Galvez MP, et al. Onset of breast development in a longitudinal cohort. *Pediatrics*. 2013;132:1019–1027

girls, a delay of longer than 4 to 5 years from onset of puberty to menarche is also cause for concern. Similarly, maturation arrest in boys warrants evaluation.

Constitutional delay, a slow maturation with appropriate hormonal levels and delayed bone age, accounts for most cases of delayed pubertal development. This problem is identified more frequently in boys than in girls, perhaps because of general societal and peer group reaction to short and sexually underdeveloped boys. The delay is frequently familial. In many instances, early signs of puberty are found on thorough examination, which permits the physician to reassure the child and the parents. Affected children should be followed closely. The presence of chronic systemic diseases that can lead to delayed puberty may be difficult to differentiate from constitutional delay as a cause for the delay.

The remainder of the differential diagnosis of delayed development relates to failure at either the hypothalamic-pituitary level, shown by low serum gonadotropins (hypogonadotropic hypogonadism), or

the gonadal level, shown by elevated gonadotropins (hypergonadotropic hypogonadism). Either of these conditions may result from genetic disorders or acquired illnesses (see Box 185-1). The workup of the patient is directed toward identifying the specific cause. Common initial screening tests are shown in Box 185-2 and include a thorough history, physical examination, and assessment of growth velocity. A bone age assessment is often helpful. For delayed development to be the result of an undiagnosed systemic illness is relatively uncommon, but if the history or physical examination suggests a systemic illness, then specific screening may include a complete blood count, electrolytes, renal and liver function tests, erythrocyte sedimentation rate and C-reactive protein, inflammatory bowel disease panel, and celiac disease panel. A screen for endocrinopathies should include thyroid-stimulating hormone and thyroid hormone levels, gonadotropins (LH, FSH), testosterone, estradiol, and insulin-like growth factor I. Other tests that a specialist may order include insulin-like growth

### BOX 185-1 Causes of Delayed Puberty

1. Constitutional delay
2. Deficiency of gonadotropin-releasing hormone secretion by the hypothalamus
  - a. Genetic and molecular causes
    - i. Isolated deficiency
    - ii. Kallmann syndrome
    - iii. Laurence-Moon-Bardet-Biedl syndrome
    - iv. Prader-Willi syndrome
  - b. Acquired causes
    - i. Infection
    - ii. Neoplasm
    - iii. Infiltrative disease
    - iv. Trauma
3. Deficiency of gonadotropin secretion by the pituitary
  - a. Genetic
    - i. Panhypopituitarism (including transcription factor mutations in *PROT1*, *HESX1*, and *LHX3*)
    - ii. Isolated deficiency
    - iii. Fertile eunuch (normal follicle-stimulating hormone, low luteinizing hormone)
    - iv. Leptin or leptin-receptor deficiency
  - b. Acquired
    - i. Infection
    - ii. Tumor
    - iii. Excess prolactin secretion, adenoma
    - iv. Trauma
4. Gonadal disorders
  - a. Genetic and molecular
    - i. Turner syndrome (45,X or structural X abnormalities or mosaicism)
    - ii. Klinefelter syndrome (47,XXY)
    - iii. Noonan syndrome
  - iv. Syndromes of complete androgen insensitivity (no sexual hair)
  - v. del Castillo syndrome (Sertoli cells only)
  - vi. Pure gonadal dysgenesis
  - vii. Myotonic dystrophy
  - viii. Receptor mutations
  - b. Acquired
    - i. Infections
      - (1) Gonorrhea (male)
      - (2) Virus (mumps, coxsackie)
      - (3) Tuberculosis (male)
    - ii. After radiation or chemotherapy
    - iii. Mechanical causes
      - (1) Torsion
      - (2) Surgery
      - (3) Congenital anorchia (vanishing testes syndrome)
      - (4) Autoimmune
5. Adrenal and gonadal steroid enzyme deficiencies
6. Excessive exercise, malnutrition
7. Chronic systemic diseases
  - a. Congenital heart disease
  - b. Chronic pulmonary disease
  - c. Inflammatory bowel disease, celiac disease
  - d. Chronic renal failure and renal tubular acidosis
  - e. Hypothyroidism
  - f. Poorly controlled diabetes mellitus
  - g. Sickle cell anemia, thalassemia
  - h. Collagen-vascular disease
  - i. Anorexia nervosa
  - j. HIV infection

factor-binding protein 3, prolactin, karyotype, brain magnetic resonance imaging (MRI), pelvic ultrasound, and GnRH testing assessing for signs of central puberty.

Treatment should be directed toward the cause of the delayed development. If sex steroid secretion is deficient as a result of either gonadal failure or gonadotropin deficiency, then treatment focuses on replacing the appropriate sex steroid. In constitutional delay, waiting may be the best course. In boys, however, a short course of low-dose injectable testosterone (eg, 50–100 mg monthly for 4 doses) may be indicated if the delayed development is affecting the boy's psychological well-being. In girls, cosmetic treatment, such as the use of a padded bra, is helpful. Estrogen therapy is necessary only occasionally. In patients who have GnRH or gonadotropin deficiency, fertility may be induced with GnRH or gonadotropin therapy. In any case, strong psychological support must be provided to the adolescent and sometimes to the family. If the problem is difficult diagnostically, or if hormonal therapy is desired, then referral should be made to a pediatric endocrinologist.

## PRECOCIOUS PUBERTY

Classically, precocious puberty is the appearance of secondary sexual characteristics before 8 years of age

in girls and 9 years in boys. But a substantial number of girls, 27.2% of black girls and 6.7% of white girls, have breast or sexual hair development by 7 years of age. As a result of these data, the Drug and Therapeutics and Executive Committees of the Pediatric Endocrine Society published recommendations proposing that the age cutoff for precocious puberty should be decreased to 7 years in white girls and 6 years in black girls unless the tempo of puberty is abnormal, the bone age is advanced more than 2 years, the predicted height is less than 150 cm (59 inches), focal neurologic deficits are present, headaches are present, or the family's or the child's emotional state is affected adversely. These recommendations are controversial, and although extensive evaluation in 6- to 8-year-old girls is usually not revealing of pathologic abnormality, each child must be considered individually.

Early stimulation of the hypothalamic-pituitary axis, with resultant gonadotropin secretion and sex steroid secretion, is termed *central precocious puberty*. Sex steroid secretion that is independent of pituitary gonadotropin secretion may be termed *peripheral* or *pseudoprecocious puberty*. Box 185-3 lists the causes of these 2 conditions. Precocity may be isosexual (appropriate for phenotype) or heterosexual (appropriate for opposite gender phenotype) and is significantly more common in girls than it is in boys. Box 185-4 lists the causes of heterosexual precocious puberty. In girls, idiopathic precocious puberty is the single most common diagnosis and accounts for 85% of central precocious puberty, whereas 60% of precocious puberty in boys has a pathologic cause. Girls adopted from developing countries may be at particular risk

### BOX 185-2 Evaluation for Delayed Puberty

#### INITIAL SCREENING TESTS (AS INDICATED)

- Thorough history, physical examination, and calculation of growth velocity
  - Bone age
  - Luteinizing hormone, follicle-stimulating hormone
  - Testosterone or estrogen, depending on gender
  - Thyroid-stimulating hormone, thyroid hormone
- If systemic disease is thought to exist*
- Complete blood count
  - Erythrocyte sedimentation rate, C-reactive protein
  - Comprehensive panel (electrolytes; renal and liver function tests)
  - Insulin-like growth factor I, insulin-like growth factor-binding protein 3
  - Urinalysis
  - Celiac disease panel (antiendomysial immunoglobulin A [IgA] antibody or tissue transglutaminase IgA and total IgA levels)
  - Inflammatory bowel disease panel
  - Prolactin

#### OTHER TESTS (IF INDICATED)

- Karyotype
- Brain magnetic resonance imaging
- Pelvic ultrasound
- Gonadotropin-releasing hormone (GnRH) or GnRH analog stimulation test

### BOX 185-3 Causes of Isosexual Precocious Puberty

1. Central (with pituitary gonadotropin secretion)
  - a. Idiopathic
  - b. Central nervous system abnormalities
    - i. Congenital anomalies (hydrocephalus)
    - ii. Tumors (hypothalamic, pineal, other)
    - iii. Hamartoma
    - iv. Postinflammatory condition
    - v. Trauma
    - vi. Syndromes
      - (1) Neurofibromatosis
      - (2) Tuberous sclerosis
  - c. Hypothyroidism (severe)
2. Peripheral
  - a. Exogenous sex steroids
  - b. Gonadal tumors or cysts
  - c. Adrenal hyperplasia or tumor
  - d. Ectopic gonadotropin-secreting tumors (chorioepithelioma, hepatoblastoma, teratoma)
  - e. Familial Leydig cell hyperplasia, receptor mutation
  - f. McCune-Albright syndrome, G-protein mutation

### BOX 185-4 Causes of Heterosexual Precocious Puberty

1. Girls
  - a. Congenital adrenal hyperplasia
  - b. Androgen-secreting tumors
    - i. Adrenal
    - ii. Ovarian
    - iii. Teratoma
  - c. Exogenous androgens
2. Boys
  - a. Estrogen-producing tumors
    - i. Adrenal
    - ii. Teratoma
    - iii. Hepatoma
    - iv. Testicular
  - b. Exogenous estrogens
  - c. Increased peripheral conversion of androgens to estrogens

for precocious puberty. Internationally adopted girls have shown a trend toward early and rapidly progressing puberty that may be related to the increased metabolic activity exhibited if catch-up growth occurs after adoption. Precocious puberty can significantly reduce adult height and can, in some cases, have an adverse effect on a child's and a family's emotional state.

### VARIATIONS OF PUBERTY

Two entities not requiring treatment are isolated premature breast development (thelarche) and isolated premature development of sexual hair (adrenarche). Premature thelarche occurs in girls between 6 months and 3 years of age. Breast development is usually moderate, often regresses, and is seen without other signs of precocious puberty. Specifically, estrogen or gonadotropin levels do not increase significantly, and statural and skeletal maturation accelerate only mildly, if at all. Premature thelarche does not progress to complete precocious puberty. Premature adrenarche usually occurs between 5 and 7 to 8 years of age. The development of sexual hair is frequently accompanied by a mild growth spurt (with slight bone age advancement) and signs of increased adrenal androgens (increased levels of plasma dehydroepiandrosterone and its sulfate to the early pubertal range). In girls, signs of increased estrogen secretion are not seen. An abnormal androgen source such as a tumor or late-onset congenital adrenal hyperplasia must be excluded. Premature adrenarche may occur in children with neurologic problems. In some girls, premature adrenarche may be a marker for future polycystic ovarian syndrome.

With both premature thelarche and premature adrenarche, careful follow-up physical examinations are necessary to be sure they do not represent the early stages of complete sexual precocity.

### BOX 185-5 Evaluation for Precocious Puberty

#### INITIAL SCREENING TESTS

- Thorough history, physical examination, and calculation of growth velocity
- Bone age
- Luteinizing hormone, follicle-stimulating hormone
- Estradiol, testosterone
- Dehydroepiandrosterone sulfate
- 17-Hydroxyprogesterone
- Thyroid-stimulating hormone, thyroid hormone

#### SECONDARY TESTS (IF INDICATED)

- Pelvic ultrasound
- Brain magnetic resonance imaging
- Serum  $\beta$ -human chorionic gonadotropin
- Gonadotropin-releasing hormone (GnRH) or GnRH

### Isosexual Precocious Puberty

Evaluation and treatment of precocious puberty are a matter for a pediatric endocrinologist. The diagnosis of isosexual precocious puberty is based on the physical examination and laboratory evidence of sex steroid secretion. Common initial tests (Box 185-5) include evaluation of growth velocity, bone age, LH, FSH, and estradiol or testosterone. Additional testing might include dehydroepiandrosterone sulfate, 17-hydroxyprogesterone, thyroid-stimulating hormone, and thyroid hormone levels. The hormone levels should be drawn as close to 8:00 am as possible to coincide with normal early-morning hormone level peaks. Other tests may include a pelvic ultrasound, brain MRI,  $\beta$ -human chorionic gonadotropin, GnRH stimulation test, or adrenocorticotrophic hormone stimulation test assessing for congenital adrenal hyperplasia. Measurement of serum gonadotropin levels before and after an injection of GnRH usually distinguishes central from peripheral precocious puberty. With central precocious puberty, further workup focuses on a search for the cause of the gonadotropin secretion. The diagnosis of idiopathic central precocious puberty can be made only after the search for a pathologic cause is negative. Although onset is at an early age, the tempo and pattern of pubertal progression are normal in idiopathic central precocity. With peripheral precocious puberty, the workup is designed to identify the source of sex steroid, remembering that exogenous sources (eg, contraceptive pills, topical androgen creams or gels) are easily available. In boys, physical examination of the testes is particularly useful in the differential diagnosis. If both testes are of pubertal size, then the patient has gonadotropin-stimulated precocious puberty; if 1 testis is enlarged, then a testicular tumor may be present; if both testes are small, then the androgens are either exogenous or of adrenal origin.

Treatment of isosexual precocity centers on suppression or removal of the underlying cause. Idiopathic

central precocious puberty is treated with GnRH analogs, which lead to pituitary desensitization and a reduction in gonadotropin secretion to prepubertal levels. Several GnRH analogs are available in intramuscular (depot), subcutaneous, and intranasal forms. Depot leuprolide is used most commonly in the United States and is usually given every 3 to 4 weeks, although longer-acting forms, which may be given every 12 weeks, are available. This treatment has been used for years, is effective, and has minimal side effects. A long-acting analog is also available as an implant (histrelin acetate) and is equally effective. For gonadotropin-independent precocious puberty, testosterone and other aromatase inhibitors (anastrozole, letrozole), spironolactone (androgen-receptor inhibitor), and ketoconazole (steroidogenesis inhibitor) may be used. McCune-Albright syndrome is an unusual syndrome of irregular café au lait spots, polyostotic fibrous dysplasia, and precocious puberty caused by a somatic mutation that can lead to constitutive activation of various glands, including the thyroid, parathyroid, adrenal, and gonad. Tamoxifen (estrogen-receptor inhibitor) has recently been shown to be an effective treatment for McCune-Albright syndrome.

### Heterosexual Precocious Puberty

Heterosexual precocious puberty is uncommon (see Box 185-4 for a list of causes). Exogenous sex steroids, including topical preparations, must be considered. The diagnostic workup centers on the search for a sex steroid-producing tumor. These patients should be referred to a pediatric endocrinologist. Treatment is aimed at removal of the sex hormone source (exogenous or tumor) or suppression with glucocorticoid replacement therapy (congenital adrenal hyperplasia).

### SUMMARY

In most cases of delayed or precocious sexual development, a thorough history and physical examination and a few basic laboratory tests identify patients who are likely to have a pathologic cause requiring referral to a pediatric endocrinologist. (See Chapter 164, Hirsutism, Hypertrichosis, and Precocious Sexual Hair Development, for further discussion of various forms of precocious sexual development.)

In all cases, along with physical care, psychological care and support are extremely important, particularly when medical therapy is only partially satisfactory.

### WHEN TO REFER

For delayed puberty

- No breast development in girls by 13 years of age
- No menarche 4 to 5 years after the onset of breast development or by 15 to 16 years of age in girls
- No testicular enlargement in boys by 14 years of age
- Maturation arrest
- Hormonal abnormalities identified by initial screening tests (see Box 185-2)
- Parental or physician discomfort

For precocious puberty

- Signs of puberty before 6 to 8 years of age in girls (see text)
- Signs of puberty before age 9 in boys
- Rapidly progressive puberty (eg, stage 3 breast when first noted)
- Heterosexual precocious puberty
- Hormonal abnormalities identified by initial screening tests (see Box 185-5)
- Parental or physician discomfort

## Chapter 186 RASH

Daniel Krowchuk, MD

Skin complaints are common in pediatrics. Surveys indicate that 10% to 20% of visits by children to outpatient facilities are associated with a dermatologic problem; it may be the primary reason for the visit, a secondary concern, or an incidental finding during physical examination. Because of the volume of skin-related problems, physicians caring for children must gain some skill in recognizing and managing the most common cutaneous disorders.

Dermatology is a visual discipline. With experience, pediatricians and other physicians can recognize most

of the common problems affecting the skin, including the subtle variations in presentation. For uncommon problems, an atlas, text, consultant, or other resource can be used to aid in identification. As in most medical specialties, an organized approach to the problem is helpful in leading to the correct diagnosis.

The approach to diagnosing skin problems in children is best based on the morphology of the patient's lesions. An appropriate history and accurate description of what is seen can usually overcome any obstacle to diagnosis.

## HISTORY

Although the diagnosis of skin lesions relies heavily on physical examination and the recognition of types of lesions, as with any problem, an appropriate, problem-oriented history is the first step in diagnosis. Some questions that may be useful and their rationale are presented in the following sections.

### History of the Present Illness

*How long have you had the rash? Has it gotten better or worse? Has it occurred in the past?* Conditions such as atopic dermatitis are chronic and recurrent, whereas others such as viral exanthems (eg, erythema infectiosum) are acute and self-limited.

*Are there associated symptoms?* A generalized erythematous macular eruption associated with fever, nasal congestion, and cough suggests the presence of a viral exanthem. Fever, petechiae, and purpura in an ill-appearing child may indicate a serious bacterial infection such as meningococcemia. Atopic or contact dermatitis and scabies characteristically produce pruritus.

*Are any medications being taken?* The onset of wheals in a child receiving an oral antibiotic might represent urticaria as a manifestation of drug allergy. Lithium can worsen acne, and minocycline may cause hyperpigmentation. Topical therapies also may be relevant to the patient's problem. Neomycin (used in certain topical antibiotic preparations), diphenhydramine (used to reduce pruritus), and certain anesthetics (used to reduce pain or pruritus), when applied topically, may induce a contact dermatitis.

*Are there factors that worsen or precipitate the rash?* The malar rash of systemic lupus erythematosus is worsened by sun exposure. For many children who have atopic dermatitis, reduced humidity during colder months is associated with an exacerbation of disease.

*What treatment has been tried, and what was its effect?* Knowing which therapies have been employed, if they were used appropriately, and if they were effective is helpful. Treatment for head lice infestation, for example, may fail if the product is applied incorrectly or if it is left on the scalp for an insufficient period. In addition, repeating a therapy is unwise if it was used correctly but proved ineffective.

### Family History

*Is there a family history of skin disease or other health problems?* Children who have atopic dermatitis often have a family history of atopic disease, including atopic dermatitis, allergic rhinitis, or asthma. If a child

is found to have multiple café au lait macules and a diagnosis of neurofibromatosis type 1 is being considered, determining whether the patient has any affected first-degree relatives is vital. Whether other family members are similarly affected is relevant when cutaneous infections or infestations are suspected. Impetigo, tinea capitis, scabies, and head lice are frequently transmitted within families.

### Social History

For adolescents, in particular, a social history may be relevant.

*Do you work after school?* Occupational exposure to greases or oils (eg, in a fast-food restaurant or car repair shop) may worsen acne.

*Have you ever been involved in a sexual relationship?* A confidential sexual history may be important. Secondary syphilis and disseminated gonococcal infection, as examples, have cutaneous manifestations, and sexual contact can lead to the transmission of molluscum contagiosum or scabies and infestation with pubic lice.

## PHYSICAL EXAMINATION

Recognizing and describing skin lesions accurately is essential to diagnosis. The first step is to identify the primary lesion, defined as the earliest lesion and the one most characteristic of the disease. Primary lesions, described later, include macules, papules, vesicles, and pustules, among others. Next, noting the distribution, arrangement, and color of primary lesions, along with any secondary change, such as crusting or scaling, is important.

### Types of Primary Lesions

Primary lesions may be flat, elevated, or depressed. Flat lesions include macules and patches. A *macule* is a small, circumscribed area of color change without elevation or depression. An example is a café au lait macule (Figure 186-1). Although specific criteria for size are lacking, a *patch* is a large macule (Figure 186-2). Elevated lesions may be solid or fluid filled. Solid lesions include *papules* (<0.5 cm in diameter), *nodules* (≥0.5 cm in diameter), *wheals* (pink, rounded, or flat-topped elevations caused by edema in the skin), and *plaques* (plateau-shaped structures often formed by the coalescence of papules) (Figure 186-3, Figure 186-4, Figure 186-5, and Figure 186-6). Elevated fluid-filled lesions are *vesicles* (<0.5 cm in diameter and filled with serous fluid), *bullae* (≥0.5 cm in diameter and filled with serous fluid), *pustules* (<0.5 cm in diameter and filled with purulent material), and *cysts* (≥0.5 cm in diameter that represent sacs containing fluid or semisolid material) (Figure 186-7, Figure 186-8, and Figure 186-9). A depressed lesion may be an *erosion* (a superficial loss of epidermis with a moist base) or an *ulcer* (a deeper lesion extending into or below the dermis) (Figure 186-10).

### Distribution

Given that certain disorders have unique patterns of distribution, noting the parts of the body involved may provide an important clue to diagnosis. For example, seborrheic dermatitis commonly involves not

**Figure 186-1** Café au lait macules in a patient who has neurofibromatosis type 1.

**Figure 186-2** A port-wine stain is an example of an erythematous patch.

only the scalp but also the eyebrows and nasolabial folds. Psoriasis also affects the scalp, but lesions are often seen in areas that are traumatized, such as the elbows and knees. Acne is limited to the face, back, and chest, sites of the highest concentrations of pilosebaceous follicles.

### Arrangement

Lesions may appear in lines (eg, vesicles in contact dermatitis from poison ivy), be grouped or clustered (eg, vesicles in herpes simplex virus infection), follow

**Figure 186-3** Neonatal acne is composed of erythematous papules and papulopustules.

**Figure 186-4** Nodules representing neurofibromas in a patient who has neurofibromatosis type 1.

a dermatome (eg, vesicles in herpes zoster), or form an annulus or ring (eg, papules in granuloma annulare or a patch in erythema migrans) (Figure 186-11, Figure 186-12, Figure 186-13, and Figure 186-14).

**Figure 186-5** Pink wheals in a patient who has urticaria.

**Figure 186-6** Scaling plaques, plateau-like lesions, are observed in psoriasis.

### Color

Although the color of a lesion may be obvious, descriptive terms that can be helpful include *skin colored*, *erythematous* (pink or red), *hyperpigmented* (tan, brown, or black), *hypopigmented* (the amount of pigment is decreased but not entirely absent), *depigmented* (all pigment is absent, as occurs in vitiligo), or *violaceous*. When erythematous lesions are observed, the examiner should note whether they blanch. The red color in skin depends on hemoglobin within red blood cells. If the red cells are within vessels (as occurs in urticaria, for example), compression of the skin forces the cells into deeper vessels, and blanching

**Figure 186-7** Vesicles, as seen here in varicella, are filled with clear or serous fluid.

**Figure 186-8** Bullae, filled with clear fluid, are observed in chronic bullous disease of childhood.

occurs. However, if the cells are outside vessels, as occurs in forms of vasculitis, blanching will not occur; nonblanching lesions are termed *petechiae*, *purpura*, and *ecchymoses*.

### Secondary Changes

Secondary changes are alterations in the skin that may accompany primary lesions. These changes, too, can be valuable in differential diagnosis. *Crusting* represents dried fluid; it is commonly seen after the rupture of vesicles or bullae, as occurs with the honey-colored crust of impetigo. In contrast, *scaling*

**Figure 186-9** Pustules are filled with purulent material. This patient has folliculitis.

**Figure 186-12** Grouped vesicles are characteristic of herpes simplex virus infection on the skin.

**Figure 186-10** Erosions, as seen in this infant who has acrodermatitis enteropathica, represent a superficial loss of epidermis.

**Figure 186-13** Herpes zoster is characterized by grouped vesicles on erythematous bases distributed along a dermatome.

**Figure 186-11** A linear arrangement of papules or vesicle often occurs in contact dermatitis caused by poison ivy.

represents epidermal fragments that are characteristic of several disorders, among which are fungal infections (eg, tinea corporis) and psoriasis. *Atrophy* is an area of surface depression from absence of the dermis or subcutaneous fat. Atrophic skin often appears thin and wrinkled. *Lichenification* is a thickening of the skin that results from chronic rubbing or scratching (as occurs in atopic dermatitis, for example); as a result, skin markings (ie, creases) appear more prominent.

## DIAGNOSIS

Once the primary lesions are identified, along with their distribution, arrangement, color, and secondary changes, these observations should be formulated into 1 or 2 sentences. For example, “Located on the extensor surfaces of the extremities are erythematous,

**Figure 186-14** An annulus (ie, ring-shaped lesion) is typical of tinea corporis.

scaling papules, and plaques. Scaling of the scalp and pitting of the nails are evident.” Such formulations assist in differential diagnosis. Identifying scaling papules and plaques, as in the previous example, places the patient’s condition into the category of papulosquamous (elevated and scaling) diseases and eliminates countless other disorders from consideration. In children, the most common papulosquamous disorders are chronic atopic or contact dermatitis, tinea corporis, and pityriasis rosea; less common conditions are psoriasis, secondary syphilis, lichen planus, dermatomyositis, and lupus erythematosus. Given the location of the lesions on extensor surfaces and involvement of the scalp and nails, psoriasis becomes a primary consideration.

Boxes 186-1 and Box 186-2 assist in differential diagnosis based on the morphology of lesions. Notably, however, these tables are not exhaustive; rather, they list the most commonly encountered disorders and a few less common ones to consider. Formulating a dermatologic differential diagnosis rests not only on the primary lesion but also on other information, such as the distribution, arrangement, and color of lesions and the presence of any secondary change. When the patient’s physical findings do not immediately make

### BOX 186-1 Differential Diagnosis of Rashes in Neonates

#### ELEVATED LESIONS

##### *Papules*

##### **Common**

- Erythematous
  - Erythema toxicum
  - Miliaria rubra
  - Acne
  - Candidiasis
  - Scabies
- White
  - Milia
- Yellow
  - Sebaceous gland hypertrophy
- Skin colored
  - Epidermal nevus
  - Skin tags

##### **Uncommon**

- Yellow
  - Juvenile xanthogranuloma
- Yellow/tan
  - Mastocytosis

##### *Nodules*

##### **Common**

- Erythematous
  - Hemangioma

##### **Uncommon**

- Skin colored
  - Condylomata acuminata
  - Dermoid cyst

- Yellow

- Mastocytosis

##### *Plaques*

##### **Common**

- Skin colored or yellow
  - Nevus sebaceus
- Skin colored
  - Epidermal nevus

##### *Vesicles or bullae*

##### **Common**

- Erythema toxicum
- Miliaria crystallina
- Sucking blisters
- Bullous impetigo
- Herpes simplex virus infection

##### **Uncommon**

- Incontinentia pigmenti
- Aplasia cutis congenita
- Varicella
- Epidermolysis bullosa
- Epidermolytic ichthyosis

##### *Pustules*

##### **Common**

- Erythema toxicum
- Transient neonatal pustular melanosis
- Miliaria pustulosa
- Herpes simplex virus infection
- Folliculitis

**BOX 186-1 Differential Diagnosis of Rashes in Neonates—cont'd**

- Acne
- Candidiasis
- Scabies

**Uncommon**

- Acropustulosis of infancy

**FLAT LESIONS****Macules****Common**

- Hypopigmented
  - Prehemangioma
  - Postinflammatory hypopigmentation
- Hyperpigmented
  - Transient neonatal pustular melanosis
  - Café au lait macule
  - Postinflammatory hyperpigmentation
  - Congenital melanocytic nevus

**Uncommon**

- Hypopigmented
  - Ash leaf macule

**Patches****Common**

- Erythematous
  - Salmon patch (nevus simplex)
  - Hemangioma (early)
  - Port-wine stain
  - Atopic dermatitis

- Seborrheic dermatitis
- Diaper dermatitis (irritant or seborrheic)
- Hyperpigmented
  - Dermal melanosis
  - Lentigo

**Uncommon**

- Erythematous
  - Acrodermatitis enteropathica
- Hyperpigmented
  - Pigment mosaicism
- Hypopigmented
  - Pigment mosaicism
  - Nevus depigmentosus

**DEPRESSED LESIONS****Erosions****Common**

- Bullous impetigo (after bullae rupture)
- Neonatal herpes simplex virus infection (after vesicles rupture)
- Staphylococcal scalded skin syndrome

**Uncommon**

- Aplasia cutis congenita
- Acrodermatitis enteropathica
- Epidermolysis bullosa
- Epidermolytic ichthyosis

**BOX 186-2 Differential Diagnosis of Rashes in Older Infants, Children, and Adolescents****ELEVATED LESIONS****Papules Without Scaling****Common**

## Chapter 187

# RECURRENT INFECTIONS

David L. Goldman, MD

Pediatric primary care physicians frequently encounter children who have recurrent infections, most of whom are otherwise healthy. Reassuring the parents of these children that no underlying abnormality exists is particularly important. Much less commonly, recurrent infections are a sign of an underlying, possibly immunologic, disorder. Early identification of these children is critical because prompt intervention can decrease morbidity and mortality.

## NORMAL PATTERN OF INFECTIONS IN CHILDHOOD

Generally, healthy children experience 6 to 8 upper respiratory tract infections per year in the first few years of life. However, up to 15 infections per year can still be within the normal range. The high frequency of infections in the first years of life results from the relative immunologic immaturity of young children and their frequent exposure to respiratory pathogens. Factors such as attendance in child care and exposure to secondhand smoke may increase the number of infections.

In the healthy host, these infections are self-limited, occur more frequently in the winter than in other seasons, and are associated with periods of wellness in between illnesses. Growth and development are normal. Considering that the average duration of a viral illness is 7 to 10 days, typically, a toddler may be sick for up to 100 days or almost one-third of the year.

## INFECTIONS ASSOCIATED WITH AN UNDERLYING IMMUNE DISORDER

Occasionally, a pediatrician will encounter a child who has a history of infections that number above the normal range. Certain patterns of infections should alert the physician to the possibility of an underlying immunodeficiency. One such pattern is an increased frequency of common infections. Although an immunocompetent child can experience a single serious bacterial infection such as pneumonia, meningitis, or osteomyelitis, repeated serious bacterial infections should alert the pediatrician to the possibility of an underlying disorder. Immunodeficiency may also cause a common infection to manifest uncommonly, with increased severity, prolonged duration, or failure to respond to appropriate treatment. Varicella, a typically benign infection in healthy, immunocompetent children, can cause overwhelming infections in children who have leukemia, and prolonged illness in children who have acquired immunodeficiency syndrome (AIDS). Immunodeficiency may also be suggested by a common infection exhibiting at an uncommon age. Thrush or candidal diaper dermatitis in children older than 1 year suggests a defect in T-cell immunity. Alternatively, immunodeficiency may produce an infection with an opportunistic pathogen (ie, *Pneumocystis jiroveci*, *Cryptococcus neoformans*). Rarely, immunodeficiency may become apparent as an infection after the administration of a live virus vaccine.

## NONIMMUNOLOGIC DISORDERS ASSOCIATED WITH ENHANCED SUSCEPTIBILITY TO INFECTIONS

Host defense against microbial pathogens involves anatomic, physiologic, and inflammatory barriers. Defects in any of these systems can lead to recurrent infections. In general, recurrent bacterial infections at

the same anatomic site that are not associated with other infections or other signs of an underlying syndrome should suggest the possibility of an anatomic defect that may be either congenital or acquired. This circumstance is true especially of children who have urinary tract infections and otitis media. About 62% of children younger than 1 year have more than 1 episode of otitis media, and 17% have 3 or more episodes. The increased susceptibility of young children to otitis media results from an age-related dysfunction of the eustachian tubes and is rarely associated with underlying immunodeficiency. Anatomic defects leading to recurrent infections may also occur in other organ systems. Recurrent meningitis may occur as the result of an occult cerebral spinal fluid leak. Recurrent pneumonia may result from various nonimmunologic causes such as alteration of the normal barrier as a result of foreign body aspiration, tracheoesophageal fistula, or gastroesophageal reflux. Impaired function of mucociliary transport, as seen in cystic fibrosis and immotile cilia syndromes, also leads to recurrent pneumonia. Besides anatomic defects, recurrent or unusual infections can also occur as a result of alteration in the normal microbial flora associated with antibiotic use (eg, *Clostridium difficile* colitis) and circulatory disorders such as venostasis.

Certain types of infection may be associated with recurrent disease in the absence of recognized immunodeficiency. Recurrent soft tissue and skin infections with *Staphylococcus aureus* and colitis with *C difficile* fit this pattern, in which recurrence is thought to result primarily from bacterial characteristics that lead to persistence despite antimicrobial therapy. Treatment is therefore directed at eliminating underlying infection.

Allergic conditions may be confused with recurrent infections. Allergic rhinitis may be misdiagnosed as recurrent upper respiratory tract infection, and asthma may be misdiagnosed as recurrent pneumonia. When repeated episodes of pneumonia are the sole presentation of recurrent infection, the physician should consider the possibility of reactive airway disease, which can produce recurrent respiratory symptoms in association with pulmonary infiltrates.

SECONDARY IMMUNODEFICIENCIES

Abnormalities of the immune system may be categorized as either primary or secondary. Secondary immunodeficiencies, more common than primary, are

either acquired or a consequence of a nonimmunologic process, including infection, malignancy, medication (ie, cytotoxic, immunosuppressive), malnutrition, splenic dysfunction, and metabolic disorders (Table 187-1). Improvements in medical care have led to an increase in the number of children with secondary immunodeficiencies, including those with organ transplants, rheumatologic diseases, and malignancies. New therapies have also led to new risk factors for unusual infections. For example, anticytokine therapies such as antitumor necrosis factor- $\alpha$  for rheumatoid diseases and Crohn disease have been associated with an increased susceptibility to tuberculosis and histoplasmosis. Similarly, the implantation of foreign materials (ie, heart valves, catheters) is associated with an increased risk for infection. Improved postnatal care has led to improved survival of premature neonates, who exhibit a variety of immune deficits that put them at increased risk for infection.

The spleen serves as a filter to remove infectious agents from the circulation and as a site for maturation of the immune response. Splenic dysfunction and its associated immunodeficiency can result from a variety of disorders, including congenital absence, surgical removal, hemoglobinopathies, and infiltrative diseases. Affected patients typically experience increased susceptibility to bacterial pathogens, especially encapsulated organisms.

Human immunodeficiency virus (HIV) infection, which produces a combined deficiency in both humoral and cellular immunity (AIDS) and is an important cause of secondary immunodeficiency, may be acquired congenitally or horizontally. Children infected with HIV can develop symptoms related to a variety of infection types (ie, opportunistic, recurrent, atypical), depending on the immune status of the child. Older children, who acquire HIV infection horizontally, may develop a primary syndrome in association with the HIV infection itself, which is clinically similar to other viral illnesses (ie, influenza, infectious mononucleosis). Recent advances in HIV therapy have helped decrease the morbidity and mortality associated with this disease, making early recognition and prompt intervention essential for optimal management. Other viral infections may impair the immune response in more subtle ways. For example, preceding influenza infection is readily recognized as a risk factor for superinfection with bacterial pneumonia.

Table 187-1      Secondary Immunodeficiencies

CAUSE	DISEASE
Infection	HIV; congenital rubella
Malignancy	Leukemia; lymphoma
Metabolic	Uremia; malnutrition; protein-losing enteropathy; diabetes; galactosemia
Chromosomal	Down syndrome; Bloom syndrome
Medications	Corticosteroids; chemotherapy; antirejection medication
Splenic dysfunction	Splenectomy; sickle cell disease; congenital asplenia

HIV, human immunodeficiency virus.

Malnutrition, resulting from protein, mineral, or vitamin deficiency, is an extremely important cause of secondary immunodeficiency in many areas of the world and has been linked to increased susceptibility to a variety of infections, including measles, pneumocystis, and tuberculosis.

PRIMARY IMMUNODEFICIENCY

Primary immunodeficiencies, far less common than secondary, are caused by intrinsic defects in the immune system that are genetically determined. Excluding selective immunoglobulin A (IgA) deficiency, primary immunodeficiencies occur at an incidence of 1 in 10,000 births. Because many of these syndromes are X-linked, boys are affected more commonly than girls. Most children who have primary immunodeficiencies are symptomatic within the first few years of life, with several exceptions, including common variable immunodeficiency and deficiencies of the terminal complement components. Primary immunodeficiencies may involve the innate or adaptive immune system and are classified by the specific component of the immune system that is affected (eg, humoral, cellular, complement, and phagocytic). As our understanding of immunity and genetics has grown, there has been increased recognition of primary immune deficiency states, including defects in the innate (eg, toll-like and dectin receptors) and cellular (eg, helper T cells subtype 17 [Th17]) immune responses. There has also been improved understanding of the basis of immunodeficiency for certain syndromes. For example, defects in the Th17 immune response are now recognized to contribute to the immunodeficiency associated with hyper-IgE syndrome. Defects in various arms of the immune system are associated with enhanced susceptibility to infections by particular types of pathogens (see later). Hence, the type of infecting pathogen may be useful in guiding the evaluation of a child with a suspected immunodeficiency. Associated clinical findings, which can be nonspecific or syndrome specific, may also suggest a primary immunodeficiency. A child who has serious recurrent infections will often experience growth failure. However, other physical, historical, and laboratory findings associated with primary immunodeficiency syndromes can be found (Table 187-2). The specific timing of infections may also serve as an important clue to the nature of

immunodeficiency. For example, antibody deficiency states are not generally recognized within the first few months of life because of the presence of maternal antibody. In contrast, severe combined immunodeficiency, complete DiGeorge syndrome, congenital neutropenia, and leukocyte adhesion defect typically present with infections early in life.

Defects in Humoral Immunity

Defects in humoral immunity, the antibody-mediated arm of the immune system, represent 50% to 70% of symptomatic primary immunodeficiencies. The defects occur at various stages of B-cell development and result in a wide variety of clinical presentations. Syndromes range in severity from a total absence of mature B cells to an isotype deficiency to a defective antibody response against polysaccharide antigens (Table 187-3). Given the protective effects of maternally acquired antibody, even the most severely affected children (eg, those who have a total absence of antibody production) do not become symptomatic until after the first few months of life. Children who have defects in the humoral immune system are characteristically susceptible to recurrent sinopulmonary infections with encapsulated bacteria, including *Streptococcus pneumonia* and *Haemophilus influenzae*. X-linked agammaglobulinemia (Bruton agammaglobulinemia), one of the first primary immunodeficiencies to be described, is associated with a complete absence of mature B cells. Affected children have poor lymph tissue development, and a physical examination may reveal the absence of lymph nodes and tonsils. Although these children are generally not more susceptible to viral illnesses, they may experience severe or persistent enterovirus and rotavirus infections. Oral vaccination with live attenuated polio (no longer available in the United States) should be avoided because of the risk for vaccine-associated disease. Persistent *Campylobacter* species infections also may occur. Children who have defects in humoral immunity are also predisposed to autoimmune disorders, such as dermatomyositis and asymmetrical arthritis. Chronic lung disease may also occur. Treatment for antibody deficiency disorders depends on the type of disorder. Lifelong replacement therapy with intravenous immunoglobulin (IVIG) is indicated for X-linked agammaglobulinemia.

Table 187-2 Signs Associated With Primary Immunodeficiencies	
SIGN	ASSOCIATED SYNDROME
Intractable diarrhea and malabsorption	SCID; XLA; CVID
Rheumatologic conditions	CVID; IgA deficiency; XLA
Hepatosplenomegaly, lymphadenopathy	Hyper-IgM syndrome
Absence of lymph tissue	XLA
Thrombocytopenia	Wiskott-Aldrich syndrome
Eczema	Wiskott-Aldrich syndrome; chronic granulomatous disease; Job syndrome
Oculocutaneous albinism	Chédiak-Higashi syndrome

CVID, common variable immunodeficiency; SCID, severe combined immunodeficiency; XLA, X-linked agammaglobulinemia.

**Table 187-3** Humoral Immunodeficiencies

SYNDROME	CLINICAL FEATURES	ASSOCIATED FEATURES
X-linked agammaglobulinemia	Susceptibility to encapsulated bacterial pathogens Sinopulmonary and gastrointestinal infections, sepsis, meningitis Enhanced susceptibility to enterovirus and rotavirus Symptomatic polio infection following live polio vaccination	Asymmetrical arthritis; dermatomyositis; malabsorption; absence of tonsils, adenoids, and lymph nodes
Transient hypogammaglobulinemia of infancy	Recurrent sinopulmonary infections; generally improves by 3–4 yr	May develop IgA deficiency
Hyper-IgM syndrome	X-linked Recurrent bacterial infections including encapsulated pathogens Infections associated with T-cell defects (eg, <i>Pneumocystis carinii</i> ) also seen	Low levels of IgG, IgA, and IgE Neutropenia, thrombocytopenia; T-cell defects
Common variable immunodeficiency	Sinopulmonary infections Bronchiectasis Giardiasis	Most common in second and third decade Noncaseating granulomas; malabsorption; autoimmune disease
IgA deficiency	Very common (1 in 400 individuals) but usually asymptomatic Recurrent pulmonary infections leading to bronchiectasis	Systemic lupus erythematosus; rheumatoid arthritis; chronic diarrhea Allergic reactions to gammaglobulin preparations IgG subclass deficiency in some
Specific antibody deficiency with normal immunoglobulins	Recurrent bacterial infections of the respiratory tract	
IgG subclass deficiency	Normal immunoglobulin levels but with impaired antibody responses to polysaccharide antigens Clinical significance not well delineated	

### Combined Defects in Cellular and Humoral Immunity

Combined defects in cellular immunity and humoral immunity make up the second largest group of primary immunodeficiencies. Isolated defects in cellular immunity, which is mediated primarily by T lymphocytes, with preserved antibody function are very uncommon because T cells play a critical role in B-cell function and development. A deficiency in the production and response to T-cell cytokines such as interferon- $\gamma$  is a rare exception. Most children with defects in T-cell immunity have associated defects in antibody immunity. In addition to bacterial infections, affected children are characteristically more susceptible to fungal, mycobacterial, and viral infections. These children may experience recurrent or persistent candidiasis (or both) in the form of thrush and diaper candidiasis. Common viral infections of childhood (eg, varicella) may cause severe or recurrent disease in affected children. Table 187-4 lists some of the more common combined immunodeficiency syndromes.

Severe combined immunodeficiency (SCID) is the prototypical combined immunodeficiency syndrome and actually represents a collection of diseases. A variety of defects may result in SCID, including those affecting the following systems: cytokine receptors, signaling pathways, enzymes of the nucleotide salvage pathway, and major histocompatibility complex. In the first few months of life, children with SCID typically experience

intractable diarrhea, failure to thrive, recurrent candidiasis, and *P jiroveci* pneumonia. Definitive therapy depends on the type of SCID and may involve bone marrow transplantation or enzyme or gene therapy.

Wiskott-Aldrich syndrome is an X-linked disorder associated with the triad of thrombocytopenia, eczema, and recurrent infections. This disorder is thought to be related to a deficiency in T-cell activation. Affected infants often experience bleeding in the first few years of life. These children may have low IgM levels but normal IgG levels.

Ataxia-telangiectasia is an autosomal recessive disorder that produces progressive ataxia, conjunctival telangiectasias, decreased IgA levels, and altered T-cell function. Children with ataxia-telangiectasia may have thymic hypoplasia, insulin resistance, or gonadal atrophy and are at increased risk for hematologic malignancies.

### Defects in Phagocytic Immunity

The phagocytic arm of the immune response includes neutrophils and monocytes. Phagocytes form the first line of defense against many pathogens and are considered part of the nonspecific immune response. Defects in phagocytic immunity range from the absence of a particular cell type (ie, congenital neutropenia, cyclical neutropenia) to defects in chemotaxis (leukocyte adhesion disorder) to defects in effector function (chronic granulomatous disease) (Table 187-5).

**Table 187-4** Combined Immunodeficiencies

SYNDROME	CLINICAL FEATURES	ASSOCIATED FEATURES
DiGeorge syndrome	Clinically variable	Hypocalcemia; hypoparathyroidism; congenital heart disease; abnormal facies
Severe combined immunodeficiency (SCID)	Increased viral and fungal infections Both B-cell and T-cell deficiencies present Includes a variety of disorders that have multiple modes of inheritance Presents early in life (within first 3 mo of age) with recurrent or severe infections with all types of pathogens	Failure to thrive; diarrhea Most common (50%) form is X-linked Thymic hypoplasia Cartilage-hair hypoplasia with certain forms of SCID At increased risk for graft-versus-host disease with red blood cell transfusions
Ataxia telangiectasia	Recurrent sinopulmonary infections	Truncal ataxia; mental retardation; thymic hypoplasia; telangiectasia of skin and conjunctiva; glucose intolerance; increased risk for malignancy
Wiskott-Aldrich syndrome	Recurrent sinopulmonary infections	Eczema; thrombocytopenia; increased risk for malignancy

**Table 187-5** Phagocytic Immunodeficiencies

SYNDROME	CLINICAL FEATURES	ASSOCIATED FEATURES
Chronic granulomatous disease (CGD)	Often X-linked Recurrent infection of skin, lungs, liver, lymph nodes, and bone Infections with catalase-positive organisms ( <i>Staphylococci</i> spp, <i>Escherichia coli</i> , <i>Aspergillus fumigatus</i> , and <i>Candida albicans</i> )	Eczema; lymphadenopathy; hepatosplenomegaly
Chédiak-Higashi syndrome	Autosomal recessive Recurrent pyogenic infections with organisms similar to those seen in CGD	Ocular albinism; lymphoreticular malignancies Neutrophils have abnormally large granules
Job syndrome	Recurrent sinopulmonary infections and skin abscesses	Eczema; red hair; coarse facies; high IgE levels
Leukocyte adhesion defect	Autosomal recessive Recurrent bacterial infections and necrotic skin lesions	Leukocytosis with absence of neutrophils at infection site Severe gingivitis with early loss of teeth Delayed separation of umbilical cord

Affected children typically experience recurrent skin infections and abscesses in addition to sinopulmonary infections. Children with defects in phagocytic oxidative burst (ie, chronic granulomatous disease) are particularly susceptible to infections caused by organisms (*Staphylococcus*, *Nocardia*, and *Aspergillus* species) that are catalase positive and thus able to degrade hydrogen peroxide. Other clinical features associated with defects in phagocytic immunity include poor wound healing, delayed umbilical cord separation, gingivitis, and eczema.

### Defects in the Complement System

Complement acts to lyse target cells and, as an opsonin, promotes the phagocytosis of microbial pathogens. Defects in the complement system are the least common among the primary immunodeficiencies. Congenital deficiencies in the late or terminal components of the complement system (C5, C6, C7, C8, and C9) are inherited as autosomal recessive traits and

result in recurrent neisserial infections. In contrast to many of the primary immunodeficiencies, terminal complement deficiencies tend to manifest in older children and in adolescents, typically with recurrent meningococcal infection (meningitis or meningococcemia) or gonococcal arthritis. Deficiency in the C3 component results in an increased susceptibility to encapsulated bacterial pathogens and may be difficult to distinguish from antibody deficiencies except that it tends to occur at an earlier age, within the first few months of life.

## EVALUATION OF THE CHILD WITH POSSIBLE PRIMARY IMMUNODEFICIENCY

### History

An evaluation for a primary immunodeficiency should be performed after nonimmunologic and secondary

**Table 187-6 Laboratory Examination**

IMMUNODEFICIENCY	SCREENING TESTS	GENERAL COMMENTS
Humoral (B cell)	Serum immunoglobulin levels (IgG, IgM, IgA)	Antibody levels must be interpreted with respect to age-appropriate values. High or low levels can be significant. Specific antibody responses must be interpreted in the context of vaccine history.
Cellular (T cell)	Antibody titers against protein (diphtheria, tetanus toxoid) and polysaccharide ( <i>Haemophilus</i> , <i>Pneumococcus</i> spp) antigens Lymphocyte count, anergy testing, lymphoproliferative assays	
Phagocytic (macrophage or neutrophil)	Complete blood count IgE level Nitroblue tetrazolium (NBT) test, flow cytometric respiratory burst assay	Total lymphocyte count is obtained by multiplying total white blood cell count by the percentage of lymphocytes. Value <1,500 mCL is considered lymphopenia. Anergy testing not reliable for children <1 yr. Abnormal neutrophil structure may be present.
Complement	CH <sub>50</sub> assay	IgE level elevated in Job syndrome.  Screening assay for components of classic complement pathway. May not be sensitive for limited deficiencies in individual complement components.

immunodeficiency syndromes have been considered. A complete history should be obtained for all children being evaluated for recurrent infections, including a history of risk factors for HIV infection (either personal for adolescents or parental when congenital transmission is a possibility): drug use, prostitution, blood-product transfusion, multiple sexual partners, or history of sexually transmitted infection and homosexual behavior. Particular attention should be paid to documenting the characteristics of previous infections, including the types of pathogens and infections, duration of illnesses, and need for hospitalizations. Because many of the primary immunodeficiencies are hereditary, a detailed family history is important. A complete review of systems should be obtained, with attention paid to known associated features of immunodeficiency syndromes, including failure to thrive. The immunization history is important because failure to make protective antibodies in response to immunizations can be indicative of immunodeficiency.

### Physical Examination

A complete physical examination should be performed. Many children who have immunodeficiency appear chronically ill. Growth parameters (height, weight, and head circumference percentiles) should be obtained to determine the presence of failure to thrive. Physical signs that may indicate underlying immunodeficiency include absence of tonsils and the presence of generalized lymphadenopathy and hepatosplenomegaly. Skin lesions (eczema, abscesses, and seborrhea) and mucous membrane involvement (telangiectasia, mucositis) are observed with some immunologic disorders. Signs of recurrent infection (eg, dull, retracted tympanic membranes) and evidence of ongoing infection (eg, thrush) may be present. Specific

signs associated with a particular immunodeficiency syndrome, such as oculocutaneous albinism in Chédiak-Higashi syndrome, may be present.

### Laboratory Evaluation and Referral

Laboratory evaluation for a child who is thought to have an immunodeficiency should be guided by the type of infections the child is experiencing. Initial screening tests usually include complete blood count and differential, serum immunoglobulin levels (IgG, IgA, and IgM), and lymphocyte count. Most primary immunodeficiency syndromes will be associated with abnormal serum immunoglobulin levels. HIV testing should be strongly considered, as indicated by the history and physical findings. In an area that has a high prevalence of HIV infection, testing should be considered even if no obvious risk factor can be identified. Other tests of humoral immunity include B-cell number, antibody levels to various antigens, and IgG subclass determinations. Tests of cellular immunity include delayed-type hypersensitivity (ie, mumps, *Trichophyton* species infection, tetanus toxoid), T-cell enumeration, and lymphoproliferative responses. Table 187-6 lists the initial screening tests to be considered for each component of the immune system. Antibody and T-cell studies must be analyzed in the context of age-adjusted normal values and may be affected by acute illnesses. Likewise, delayed-type hypersensitivity responses are unreliable in children younger than 1 year. Radiologic studies are used primarily in the diagnosis or management of associated infections, although the absence of a thymic shadow can be indicative of DiGeorge syndrome or SCID. Regardless of the results of initial screening tests, referral to a specialist, either immunologist or infectious diseases expert, should be considered for children who have signs and symptoms suggestive of immunodeficiency (Box 187-1).

**BOX 187-1 Reasons for Referral for Suspected Immunodeficiency**

- Recurrent serious (ie, sepsis, pneumonia, meningitis) bacterial infection
- Serious bacterial infection in the context of failure to thrive
- Infection with an opportunistic pathogen (ie, *Pneumocystis*, *Cryptococcus* spp infection)
- Vaccine-associated infection
- Unusual age for infection (ie, early zoster, late thrush)
- Unusual severity or chronicity for a given infection
- Family history of immunodeficiency

**Treatment**

Treatment of primary immunodeficiency is condition specific. Patients with humoral and combined immunodeficiencies may benefit from the administration of IVIG as replacement therapy. The initial regimen is 300 to 400 mg/kg every 3 to 4 weeks and should be adjusted based on the patient's response. The trough concentration of antibody should be at least 500 mg/dL. Replacement IVIG is not indicated for all types of humoral deficiency. Furthermore, patients with IgA deficiency may develop anaphylaxis to certain brands of IVIG that contain small amounts of IgA. Other therapies include bone marrow transplantation (SCID, Wiskott-Aldrich, DiGeorge syndrome), enzyme replacement (certain forms of SCID), and cytokine therapy (interleukin-2 deficiency). Recently, interferon- $\gamma$  treatment has been demonstrated to decrease the number of infections in patients with chronic granulomatous disease. The genetic basis for many of the primary immunodeficiencies is now known, and prenatal screening is increasingly available.

Pending a complete immunologic evaluation, children who are thought to have immunodeficiency syndromes should not receive live attenuated vaccines, such as varicella and measles, to avoid the possibility of vaccine-associated infection. Vaccine recommendations for specific immunodeficiencies can be found in the American Academy of Pediatrics *Red Book: Report of the Committee on Infectious Diseases*. Blood transfusion, when needed, should be with cytomegalovirus-negative, irradiated cells to prevent the possibility of cytomegalovirus infection and graft-versus-host disease.

**Chapter 188****RED EYE/PINK EYE**

Judith B. Lavrich, MD; Sebastian Heersink, MD

Red eye in children can be difficult to diagnose and manage because, as a physical finding, it has many possible causes, variable presentations, and severity ranging from asymptomatic to vision threatening. The most common causes of a red eye in a child are infectious (bacterial, viral, or parasitic); inflammatory; allergic; traumatic, from a foreign body and corneal abrasion; or related to an underlying systemic cause. In general, red eye associated with pain, photophobia, or blurry vision indicates a serious ocular disease and should be considered for referral.

The first step in determining the cause of a child's red eye is identifying the location of the redness and swelling: is it isolated to the eyelid itself, or does it involve the conjunctiva, either diffusely, or focally around the cornea (ciliary flush, Figure 188-1)? The location provides clues to the underlying problem, which helps direct the history taking and organize the differential diagnosis. (See Table 188-1.)

**HISTORY**

A detailed history should be obtained, with specific attention paid to the onset and progression of the redness, prior episodes of redness, possible trauma or injury, prior ocular surgery, use of contact lenses, and personal contact with similarly affected individuals. In young children, the history of trauma or chemical injury can be difficult to obtain, so this possibility needs

**Figure 188-1** Ciliary flush.

**Figure 188-2** Foreign body in the conjunctiva.

Table 188-1	Causes of Red Eye by Location of Redness
Eyelid	Preseptal cellulitis Orbital cellulitis Eyelid tumors Allergic dermatitis Chalazia and hordeola Blepharitis
Conjunctiva	Trauma Viral Bacterial Chemical Allergic Vernal Phlyctenulosis Subconjunctival hemorrhage Papilloma
Cornea	Abrasion Corneal infection: bacterial, viral, fungal, or parasitic
Intraocular	Foreign body Iritis, uveitis Hyphema
Focal inflammation over involved area	Scleritis Episcleritis Ocular myositis

**Figure 188-3** Corneal abrasion.

to be considered on examination. Symptoms including itching, pain, photophobia, visual disturbance, tearing, mucous discharge, nasal discharge, and fevers should be elicited. In cases in which both eyes are affected, the sequence and timing of symptom onset are important to know: did both eyes become red initially, or was one affected before the other?

**PHYSICAL EXAMINATION**

If possible, assessing visual acuity should be the first step of any eye examination. In small children, the ability to fixate on and follow a toy is often all that can be gathered about their vision. Careful examination of ocular structures with a penlight should be next.

Starting with the lids, look for redness, crusting, clogged meibomian glands, redness at the lid margin, and thickening of the lid margin. Next, moving inward toward the eye, examine the conjunctiva, including everting the lids and looking for a foreign body (Figure 188-2). To look under the upper lid, place a cotton-tipped swab on the outside of the upper lid 1 cm above the lash line and gently evert the lid over the cotton swab. (This technique is demonstrated at [www.nlm.nih.gov/medlineplus/ency/imagepages/19662.htm](http://www.nlm.nih.gov/medlineplus/ency/imagepages/19662.htm).) Then, determine whether the conjunctival redness is diffuse or sectoral. Fine follicles in the conjunctiva overlying the lid indicate a viral infection, whereas edema suggests allergic conjunctivitis. The cornea should then be evaluated for opacities, foreign bodies, and disruption of the light reflex. The use of fluorescein and a cobalt blue light can highlight any corneal abrasions (Figure 188-3). Next, examine the pupils: check for size, shape, and reactivity. A mid-dilated pupil would suggest iritis. An irregular pupil may suggest trauma and possible intraocular foreign body. Beyond the eye, attention should be paid to

preauricular lymph nodes (viral conjunctivitis), stiff or tender joints (juvenile idiopathic arthritis, or JIA).

## DIFFERENTIAL DIAGNOSIS AND MANAGEMENT

### Eyelid Abnormalities

#### Preseptal and Orbital Cellulitis

Signs of preseptal cellulitis include tenderness, conjunctival swelling, and redness. As the name suggests, preseptal cellulitis (Figure 188-4) occurs anterior to the orbital septum, and therefore has *no* associated double vision, decreased vision, proptosis (eyeball pushed forward), limited motility, or pain with eye movement. These signs would indicate a more severe condition with orbital involvement. Common causes of preseptal cellulitis in children are trauma (laceration, insect bite, or puncture wound) or adjacent infections (sinusitis, herpetic dermatitis, infected chalazion, or dacryocystitis—an infected tear drainage duct) (Figure 188-5). For patients with mild to moderate preseptal cellulitis, laboratory evaluation is not usually needed. For highly febrile patients or severe preseptal cellulitis, a complete blood cell count (CBC) and blood culture should be considered. A computed tomography (CT) scan with contrast of the orbits and sinuses provides details related to bony structures or radiopaque foreign bodies and should be performed in cases of significant trauma or suspected foreign body, sinus disease, suspected orbital involvement, or abscess formation.

Signs of orbital cellulitis may include tenderness, conjunctival swelling and redness, double vision, decreased vision, proptosis, limited motility (Figure 188-6), pain with eye movement, fever, and in severe cases, pupillary involvement. The most common cause of orbital cellulitis in children is concomitant sinus disease with penetration through the thin bones of the orbital walls; but it can also result from dental infection, hematogenous spread, or orbital trauma. In cases of suspected orbital cellulitis, vital signs, mental status, neck flexibility, and facial sensation should be evaluated. Laboratory evaluation should include a CBC and blood culture. Computed tomography scanning of the orbits and sinuses with and without contrast should be performed to evaluate for foreign bodies, sinus disease, and abscess formation. Orbital tumors such as neuroblastoma, rhabdomyosarcoma, and lymphangioma can masquerade as orbital cellulitis. For better delineation of soft tissue details, and particularly if the physician also suspects an intracranial complication, magnetic resonance imaging may be needed. Admission for broad-spectrum intravenous antibiotics and possible surgical drainage is mandatory.

#### Eyelid Tumors

Capillary hemangiomas (Figure 188-7) and the port wine stain of Sturge-Weber syndrome can cause redness and swelling of the lid. In these conditions, which progress slowly over months, the visual axis can become obstructed leading to amblyopia—affected patients should be referred to an ophthalmologist for evaluation.

**Figure 188-4** Preseptal cellulitis.

**Figure 188-5** Dacryocystitis.

**Figure 188-6** Orbital cellulitis.

### Allergic Reactions

Contact dermatitis (Figure 188-8), insect bites, or bee stings can mimic preseptal cellulitis but can be differentiated by the significant itching, limited pain, and boggy rather than tense edema. Treatment options

**Figure 188-7** Capillary hemangioma.

**Figure 188-9** Chalazion.

**Figure 188-8** Contact dermatitis.

include oral antihistamines, topical or oral steroids, and cool compresses.

### **Hordeola and Chalazia**

Hordeola, commonly known as styes, and chalazia are localized inflammatory reactions to blocked oil glands (meibomian glands) in the eyelid margin. These lesions have focal areas of tense, firm, and often painful swelling with visible concretions in the oil glands near the areas of swelling (Figure 188-9). Treatment includes hot compresses with light massage and an antibiotic ointment (erythromycin, bacitracin) applied to the eyelash margin twice daily. If there is no resolution in 4 to 6 weeks, or if there is significant worsening, patients should be referred for evaluation of possible surgical drainage.

### **Blepharitis**

Blepharitis is a common, chronic inflammation and redness of the eyelid margin with blockage of the meibomian glands and associated crusting of the lashes. It is treated with lid scrubs using nonirritating products such as baby wash or baby shampoo to remove crusting, warm soaks to help drain the meibomian glands, and antibiotic ointment to the lids to reduce the bacterial load on the skin.

### **Trauma**

Trauma to the eye often leads to edema and ecchymosis of the eyelids, making examination difficult. The lids may be so tense that a lid speculum may be needed to open them, if the physician is comfortable using this instrument. If the eyelids cannot be opened with effort, a retrobulbar hemorrhage should be suspected, and emergent ophthalmologic consult should be obtained. Avoid putting any pressure on the eye until it is confirmed that the globe is intact.

### **Conjunctival Abnormalities**

Conjunctival redness can be either focal or diffuse, and the differential diagnosis includes viral or bacterial infection, chemical exposure, an allergic reaction, subconjunctival hemorrhage, a viral papilloma, or Kawasaki disease. For an overview of distinguishing characteristics among causes of conjunctivitis, see Table 188-2. Rarely, nondraining conjunctivitis can be caused by leptospirosis, tularemia, or toxin-mediated staphylococcal or streptococcal disease.

### **Viral Conjunctivitis**

The most common cause of conjunctivitis is a viral infection. Viral conjunctivitis is often highly contagious. Adenovirus is the most common viral pathogen. Rarely, herpes simplex virus (HSV) can cause conjunctivitis, but there are often typical HSV satellite lesions on the skin near the eye. Corneal involvement may also occur with HSV and is often accompanied by photophobia and more intense pain. (See Herpetic Keratitis.) Spreading through the copious watery discharge of an infected individual from eye to hand to eye, viral conjunctivitis quite commonly affects entire households or sports teams. In addition to itching, burning, or gritty sensation that typically starts in 1 eye and involves the fellow eye 2 to 5 days later, patients often complain of watery discharge, rhinorrhea, and sore throat. Patients can sometimes recall a recent exposure to a sick contact or someone with a red eye. There is often preauricular lymphadenopathy, and the conjunctiva will often have follicles, or bumps of lymphoid aggregates best seen with

**Table 188-2** Differentiating Types of Conjunctivitis

	BACTERIAL	VIRAL	ALLERGIC	PROBABLE REFERRAL
<b>Presentation</b>	Unilateral or bilateral	Usually unilateral, then spreads to other eye	Usually bilateral; can be unilateral	
<b>Season</b>	Common in winter	Spring or fall	Spring or fall	
<b>Onset</b>	Concurrent with otitis media	Concurrent systemic viral infection	Acute or chronic	
<b>Symptoms</b>	Crusting on eyelashes Gluey or sticky eyelids ± fever	Tearing Eye irritation ± fever	Itching Swelling of lids Conjunctival edema	Light sensitivity Pain Blurred vision
<b>Discharge type</b>	Purulent, thick, yellow/green	Serous or mucoid	Stringy, whitish, ropey, if any	
<b>Patient type</b>	Younger children Contact lens wearer	Any age	>2 yr	Red eye for ≥2 wk
<b>Examination findings</b>	Papules on conjunctiva	Follicles on palpebral conjunctiva Frequent preauricular nodes	Conjunctival edema and injection	

fluorescein (Figure 188-10). Severe cases sometimes have pseudomembranes of fibrin that cause scant bleeding when removed with cotton tips, as well as corneal subepithelial infiltrates, aggregates of immune cells. These signs occur 1 to 2 weeks after onset of symptoms and warrant referral to an ophthalmologist. Treatment is supportive, with a focus on minimizing contagion. Patients and parents should be instructed to wash their hands often and not share towels or bed linens. In the absence of systemic signs of illness such as fever, children with conjunctivitis should not be removed from school unless they are unable to participate in activities, the care of their classmates would be compromised by their need for special attention, or their exclusion has been recommended by a physician or department of health. In group care settings, if 2 or more children are infected with conjunctivitis at the same time, it is appropriate to seek the advice of a health care provider or department of health.

For nonspecific viral conjunctivitis or adenovirus, chilled preservative-free artificial tears 4 to 8 times a day and cool compresses several times a day are recommended for symptomatic relief. Currently, topical ganciclovir ophthalmic gel is being used off-label to treat adenoviral infections, as recent small case studies have shown its effectiveness. HSV conjunctivitis should be referred to an ophthalmologist for a more complete examination and antiviral therapy because it can be a vision-threatening infection.

### Bacterial Conjunctivitis

Compared with viral conjunctivitis, bacterial conjunctivitis is less common and often has a purulent rather than a watery discharge (Figure 188-11) and less of a follicular reaction. Cultures are not routinely performed. Common bacteria include *Staphylococcus aureus*, *Staphylococcus epidermidis*, *Streptococcus pneumoniae*, and *Haemophilus influenzae*. Topical antibiotic treatment

**Figure 188-10** Viral conjunctivitis.**Figure 188-11** Bacterial conjunctivitis.

is often successful, either with drops (trimethoprim-polymyxin B, moxifloxacin, or gentamicin 4 times a day for 7 to 10 days), or with an ointment (bacitracin-polymyxin B or erythromycin 4 times a day for 5 to 7 days). A fluoroquinolone gel (besifloxacin) is also approved for use, twice daily for 7 days.

In neonates with conjunctivitis, bacterial infection must be ruled out. With a hyperacute onset and copious discharge, gonococcus should be the first consideration because it can perforate a healthy cornea within 24 hours. Gonorrheal infection usually manifests 3 to 4 days after birth. Chlamydial infection can cause pneumonia as well as conjunctivitis and usually occurs within the first month of life. Cultures should be taken with special media. Presumptive treatment pending culture results involves intravenous ceftriaxone for *Neisseria gonorrhoeae* and oral erythromycin for chlamydia. Erythromycin has been associated with infantile hypertrophic pyloric stenosis (IHPS) when administered to infants younger than 6 weeks. Because the risk for IHPS after azithromycin has not been established and at least some evidence suggests it may be lower, some physicians prefer it in place of erythromycin, which the American Academy of Pediatrics continues to recommend. An ophthalmology consultation should be considered.

Of note, nasolacrimal duct obstruction, like bacterial conjunctivitis, can produce mucopurulent drainage, but the conjunctiva typically remains white and noninflamed. Pressure over the nasolacrimal sac, inferior to the medial canthus, will cause reflux of watery mucoid discharge.

In teenagers, bacterial conjunctivitis can represent a sexually transmitted disease, either gonorrhea or chlamydia. Gonorrhea typically produces hyperacute conjunctivitis with copious purulent discharge. Cultures should be taken, and the patient and sexual partners should be treated systemically for gonorrhea, usually with ceftriaxone. Chlamydia usually causes a chronic conjunctivitis with scant discharge and beefy inflamed conjunctiva. It should be suspected when topical antibiotics fail to improve a bacterial conjunctivitis. Treatment of patient and contacts is with oral azithromycin or doxycycline; however, the latter should be avoided in children younger than 8 years because of potential permanent staining of teeth.

### Chemical Conjunctivitis

Exposure to a chemical irritant can produce rapid conjunctival inflammation. For children who have gotten a household chemical into an eye, the most important treatment is immediate and copious irrigation with the nearest source of water. When the child is brought to medical attention, the pH of the conjunctival surface should be checked (basic solutions penetrate deeper and cause more damage than acids), and irrigation should not be discontinued until the pH remains 7.0 for several minutes after an interruption. If there are areas of white clear conjunctiva or corneal clouding, which suggest necrosis, the child should be urgently referred to an ophthalmologist for aggressive treatment. In most cases, however, artificial tears and topical antibiotic eyedrops are sufficient.

### Allergic Conjunctivitis

Allergic conjunctivitis may be acute or chronic, but it is almost always associated with itching. Discharge may be clear, with some mucus, or stringy and white. Conjunctival edema with associated redness may appear as an intensely swollen eye (Figure 188-12). Treatment of allergic conjunctivitis includes cool compresses, topical antihistamines and mast cell stabilizers, oral antihistamines, topical steroids, and rarely oral steroids.

Vernal conjunctivitis is a subset of allergic conjunctivitis that occurs most often in the springtime every year in young boys with a family history of allergies. On examination, there is often a ring of swollen, gelatinous conjunctiva with or without whitish-yellow deposits, and papillae are common on the tarsal conjunctiva (Figure 188-13).

Phlyctenulosis, another subset of allergic conjunctivitis, is a delayed hypersensitivity reaction that is often bilateral and results in a white, raised lesion on either

**Figure 188-12** Allergic conjunctivitis.

**Figure 188-13** Vernal conjunctivitis.

the conjunctiva or peripheral cornea, with dilated blood vessels at its borders (Figure 188-14). The most common precipitant is exposure to staphylococci, but it can also be associated with tuberculosis or histoplasmosis, so in cases without signs of blepharitis, a test for tuberculosis and a chest radiograph are warranted. Treatment is the same as for blepharitis, with the addition of interventions to treat the allergic component. Patients with significant irritation may require topical steroids and should be referred.

### **Subconjunctival Hemorrhage**

Subconjunctival hemorrhage is easily diagnosed by its often strikingly large patch of bright red on an otherwise white conjunctiva, usually in an asymptomatic patient (Figure 188-15). It can occur after a vaginal delivery, with Valsalva maneuver, with use of antiplatelet medications, from a severe cough as with pertussis, or from trauma. Nonaccidental trauma should be considered in atypical cases. When there are recurrent subconjunctival hemorrhages, a bleeding disorder or blood dyscrasia should be considered. No treatment is needed for a subconjunctival hemorrhage,

**Figure 188-14** Phlyctenule.

which will resolve over 2 to 3 weeks. It is worth counseling patients and parents that, as with most ecchymoses, the lesion may expand slightly and change colors as it resolves.

### **Conjunctival Papilloma**

Commonly a benign, self-limited lesion caused by human papillomavirus 6 or 11, a conjunctival papilloma is a fleshy nodule with a sunburst vascular pattern (Figure 188-16). For large, multiple, recurrent, or cosmetically disturbing lesions, treatment options include cryotherapy, surgical excision, and oral cimetidine.

### **Kawasaki Disease**

The bilateral nonexudative conjunctivitis of Kawasaki disease, an acute vasculitis, is associated with fever, mucosal erythema, rash, cervical lymphadenopathy, and the potential for coronary artery aneurysms. The conjunctivitis is usually self-limited and can be treated with artificial tears.

### **Corneal Abnormalities**

#### **Corneal Abrasion/Foreign Body**

Corneal abrasions classically have a very painful presentation, and the patient will complain of a foreign body sensation, tearing, and often photophobia. Patients often recall a sudden onset after being hit or scratched in the eye. Examination is often difficult, but instillation of anesthetic drops, such as proparacaine 0.5%, facilitates examination. The corneal abrasion is easily identified with a Wood lamp and fluorescein. In patients with a corneal abrasion, a foreign body should be suspected, and the undersurface of the eyelids should be examined. A corneal foreign body (Figure 188-17) can be removed with a moist cotton-tipped applicator if superficial, but deeper ones should be referred to an ophthalmologist.

#### **Corneal Ulcer**

Bacterial, fungal, viral, or parasitic organisms can cause ulceration, a sight-threatening condition that requires urgent ophthalmologic evaluation if there is corneal opacity, decreased vision, or ocular pain

**Figure 188-15** Subconjunctival hemorrhage.

**Figure 188-16** Conjunctival papilloma.

**Figure 188-17** Corneal foreign body.

**Figure 188-18** Corneal ulcer.

(Figure 188-18). Because contact lenses are a significant cause of corneal infections, an ophthalmologist should evaluate patients who develop a red eye and wear contact lenses.

### **Herpetic Keratitis**

Both HSV and varicella-zoster virus (VZV) can infect the eye. Whereas VZV typically spreads to the eye from the face or eyelid, HSV can infect the cornea directly. Examination of the cornea with fluorescein reveals a dendritic branching epithelial defect (Figure 188-19). If herpes is suspected, an ophthalmologic evaluation is urgently warranted to evaluate for intraocular involvement and intraocular pressure elevation. Treatment of both HSV and VZV involves either oral antivirals (acyclovir, valacyclovir) or topical antiviral eyedrops (trifluridine) or gel (gancyclovir). If patients with a history of herpetic keratitis develop red eye, they should be seen by an ophthalmologist because recurrence is common. Corneal HSV disease often causes corneal scarring, which can be sight threatening.

**Figure 188-19** Herpetic keratitis.

### **Intraocular Abnormalities**

Corneal and ciliary flush (Figure 188-1) is a violaceous, extreme engorgement of vessels at the corneal limbus that indicates involvement of deeper ocular structures. A patient with this finding should always be referred to an ophthalmologist. The differential diagnosis includes corneal infection, iritis, uveitis, and hyphema.

### **Iritis/Uveitis**

Iritis and uveitis are inflammatory disorders within the eye often associated with sarcoidosis, HSV, syphilis, tuberculosis, lupus, or autoimmune arthritides—including JIA and the HLA-B27–positive spondyloarthropathies. Affected patients complain of photophobia, pain, and blurred vision and usually have ciliary flush and a mid-dilated pupil. In patients with a first episode of unilateral iritis, no workup is indicated because it will have an unidentified cause. However, in the case of recurrent or bilateral disease, or if the medical history suggests a systemic disorder, an underlying cause should be sought and treated. The laboratory workup includes antinuclear antibody, erythrocyte sedimentation rate, serum uric acid level, antineutrophil cytoplasmic antibody, rapid plasma reagin, and fluorescent treponemal antibody absorption. In children with JIA, frequent screening for uveitis is critical because the inflammation is commonly asymptomatic with few external findings and if left untreated can lead to blindness. Young patients with pauciarticular JIA should be evaluated every 3 months for 7 years. Treatment includes topical and/or oral steroids to control the disease and cycloplegia to prevent iris adhesions and reduce photophobia. In the event of long-term steroid use, intraocular pressure should be monitored.

### **Hyphema**

A hyphema is blood collected in the anterior chamber of the eye, which is located behind the cornea and in front of the lens (Figure 188-20). In children it is almost

**Figure 188-20** Hyphema.

exclusively a result of trauma, but in the absence of trauma, tumors and coagulopathies should be suspected. Affected patients should be referred to an ophthalmologist because treatment includes monitoring of intraocular pressure, cycloplegia to prevent iris movement and adhesions, topical steroids to decrease inflammation, and reduced patient activity to prevent a rebleed.

#### Other Inflammatory Conditions

Scleritis, episcleritis, and ocular myositis are rare inflammatory conditions that cause a focal conjunctival redness. Episcleritis and scleritis can be distinguished because episcleritis has minimal discomfort, in sharp contrast to the severe pain of scleritis. The inflammation of myositis is seen overlying the affected extraocular muscle, and often patients develop a head tilt to avoid using the sore muscle. The workup for these conditions is the same as for recurrent iritis. Treatment of episcleritis includes oral nonsteroidal anti-inflammatory drugs (NSAIDs, eg, ibuprofen) alone or accompanied by topical steroids. For scleritis and ocular myositis, ophthalmologic consultation should be obtained: treatment typically begins with NSAIDs; but if there is no improvement, systemic steroids with possible steroid-sparing immunosuppressive agents should be used.

In conclusion, the pediatrician can successfully perform the diagnosis and management of the red eye in children when attention is paid to the history, location of redness, and ocular structures involved. Accurate diagnosis allows for appropriate treatment and the proper timing of referrals.

#### Chapter 189

### SCHOOL ABSENTEEISM AND SCHOOL REFUSAL

Ronald V. Marino, DO, MPH

A major developmental task of childhood is separating from the family and accepting the functional demands of society. One of the most obvious indicators that this process may not be proceeding normally is lack of attendance at school. Assessing a child's school attendance and functioning in the context of biopsychosocial health supervision is the responsibility of child health professionals.

Nonattendance may be the consequence of a variety of underlying causes. *Absenteeism* is generally considered to be parentally sanctioned nonattendance, most commonly attributed to medical illness. *Truancy* is nonattendance without parental consent, in which the time allegedly spent at school is often spent engaging in antisocial behaviors or rebelling against authority. *School refusal* is characterized by inappropriate fear about leaving home, inappropriate fear of school, or both.

#### ABSENTEEISM

Excessive absenteeism is important to health care professionals because it is an excellent marker for both physical and mental health problems (Box 189-1). It also is negatively correlated with social adjustment and academic performance. In fact, excessive absenteeism and failure to read at the appropriate level in the third grade are the 2 strongest predictors of subsequent dropping out of school. According to the National Center for Education Statistics for 2005, 19% of fourth-graders and 20% of eighth-graders missed at least 3 days of school in the past month. More specifically, 7% of fourth-graders and 7% of eighth-graders missed at least 5 days of school in the past month. National surveys indicate that healthy children average 4 or 5 absences a school year, whereas children who have a chronic disease typically are absent at least twice as often. Educators think that missing more than 10 days in a 90-day semester results in difficulty staying at grade level.

Acute physical health problems are given as the reason for nonattendance 75% of the time. However, the variability in absenteeism among children who have the same medical condition suggests that individual and family responses to the physical condition are more important than the actual condition in determining attendance. The decision not to attend school reflects subtle and complex relationships among the physical, social, and psychological states of the student, family, and community. Individual rates of absenteeism tend to be stable for a given child and also for a given school district.

The health conditions most commonly associated with nonattendance include upper respiratory tract infections, headaches, abdominal distress, menstrual cramps, and sleep disorders. Parental characteristics associated with excessive absenteeism include lower

### BOX 189-1 Chronic School Absence: Differential Diagnosis

- School refusal
- Parental overresponse to minor illnesses
- Chronic physical disease with poor adaptation
- Learning disability with poor adaptation
- Untreated mental health issues (eg, anxiety, depression)
- Bullying
- Truancy
- Substance abuse
- Psychosis
- Teenage pregnancy
- Family dysfunction (including violence and abuse)

socioeconomic class, cigarette smoking, chronic parental illness (including mental illness), lower educational expectations, and vulnerable child syndrome. A plethora of nonmedical conditions, including transportation difficulties, illness of other family members, religious holidays, family vacations, inclement weather, and professional appointments, are also reasons children miss school. Chronically ill children typically miss more school than their healthy peers. This tendency may result from a wide variety of causes, including acute exacerbations of the underlying condition, health care visits, side effects of medications, and parental misconceptions about the child's ability to attend school. Healthy adjustment by the child and family to the chronic condition minimizes the potential effect of the increase in school days missed. A significant increase in absenteeism over baseline is always a warning sign. Exploring the reasons why a particular child seeks to avoid school is the physician's responsibility. Sudden changes in school attendance may be the first concrete symptom of family dysfunction, mental illness, physical deterioration of the student or a family member, alcohol or drug abuse, or school refusal.

## SCHOOL REFUSAL

Difficulties attending school despite caretakers' support have been a problem for children, families, schools, and physicians since the early 20th century. Initial views of school refusal focused on truancy and its link to delinquency. In 1932, Broadwin focused attention on the frequent role of anxiety in attendance difficulties, and, in 1939, Patridge labeled this clinical condition *psychoneurotic truancy*. Johnson et al introduced the term *school phobia* in 1941, stressing that the child's anxiety about separating from mother was displaced to fear of attending school. This view was strengthened further in the 1950s, when Estes et al concluded that school phobia was a variant of separation anxiety.

This view and nomenclature persisted until the late 1970s, when the term *school refusal* was introduced.

The term has descriptive merits that recognize the heterogeneity of the underlying disorders. These disorders include, but are not limited to, major depression, simple and social phobia, or separation anxiety disorder. Criteria for making this diagnosis include severe difficulty in attending school or refusal to attend school, severe emotional upset when attempting to go to school, absence of significant antisocial disorders, and staying at home with the parent's knowledge.

A variety of physical symptoms often accompany the child's request to not attend school. Symptoms can be quite impressive to parents and may emulate organic medical problems.

## Prevalence

The prevalence of school refusal varies widely and has been estimated to be between 0.4% and 18%. The incidence of school refusal has 2 peaks—the first is associated with entering primary school (4–6 years), and the second is at the age of 11 to 12 years, a time of change from elementary to intermediate school, as well as the onset of early adolescence. The American Academy of Pediatrics estimates that 5% of elementary school children and 2% of junior high students experience this disorder. The symptoms of school refusal are associated with several psychiatric disorders. In an outpatient sample of referred children, 22% had separation anxiety disorder, 11% had generalized anxiety disorder, 8% had oppositional defiant disorder, and 5% had major depressive disorder. Of note is that 20% to 30% of school-refusing children do not qualify for any specific psychiatric diagnosis.

## Child-Related Factors

Children who have school refusal usually have at least average intelligence and academic achievement. Cultural norms encourage girls to admit fear and discourage boys from doing the same. The actual incidence of school refusal is nearly identical between the sexes. Younger children report more fear of being scolded or of performing before a group, whereas older children seem to be more intimidated by tests and the possibility of failure. Vague somatic symptoms, typically offered as a rationale for nonattendance, may belie the underlying anxiety that is frequently present. Symptoms may amplify in response to parental pressure to attend and/or excel in school. Overdependency or concern about the well-being of a parent is also a common underlying dynamic. Serious or chronic illness in the parent may lead to school refusal. Depression has often been noted, as have panic disorder and agoraphobia. Because there are reports of suicide among school refusers, any reference to this possibility must be addressed seriously.

## Family Factors

The family context is always a major factor because marital conflict or constricted communication patterns are often found in families with school refusers. The child's presence at home as a result of physical illness may provide a cohesive force to an otherwise unstable marital relationship. Families of youths with

school refusal behavior are often marked by poverty, poor cohesion and considerable conflict, enmeshment, isolation and detachment.

Common patterns of communication in families in which school refusal occurs have been described: Both parents are overly concerned and solicitous of the child's medical problem; 1 parent, typically the mother, is overprotective and concerned, whereas the other overtly disagrees; and 1 parent, typically the mother, is overinvolved in caring for the child's every need, whereas the other parent is emotionally absent. Because children are reared in many diverse family situations, physicians must remain open and attentive to family structure and dynamics in order to develop an effective treatment plan.

### School Environment Factors

The role of the school environment in school refusal has received little attention. Institutional factors such as changing classrooms or lack of privacy in the school bathroom have been associated with fear of school. The physical environment may include uncomfortable temperatures, mold, or allergens, which predispose to illness or student discomfort. Humiliation caused by an insensitive teacher may also be a precipitating stressor in the onset of clinical symptoms. Temperamental mismatch among teacher, student, and parents may serve a maintaining role.

Bullying and social humiliation are increasing in frequency and victims often develop somatic symptoms as a coping mechanism. The increased use of social media has created a new and potentially dangerous phenomenon in cyber bullying. Cyber bullying is defined as willful and repeated harm inflicted through the use of computers, cell phones, and other electronic devices. More than 20% of 4,400 randomly selected 11- to 18-year-olds indicated they had been subjected to cyber bullying at some point in their lives. In 2005, 24% of students aged 12 to 18 years reported gangs at their schools; this was more common among urban (36%) than suburban (21%) or rural (16%) schools. In addition, 28% of students aged 12 to 18 years were reportedly bullied at school in the past 6 months. Most said bullying occurred 1 to 2 times in 6 months, but 25% were bullied 1 to 2 times per month, 11% were bullied 1 to 2 times per week, and 8% were reportedly bullied almost daily. Both traditional and cyber bullying have been implicated as sources of severe emotional distress among victims, even leading to suicide. Violence in secondary schools provides children a seemingly appropriate reason for refusing to attend school. Twenty-six percent of junior and senior high school students have been assaulted on school grounds, 20% of students admitted bringing a knife or gun to school, and 10% admitted not going to school because of fear of violence. Media attention to school violence may further accelerates a child's anxiety and school refusal. Clearly, school-associated stressors are emerging as a concern in understanding and treating school refusal.

### Associated Stressors

While exploring factors related to the child, parent, family, and school environment, the physician must

also search for a precipitating event or stress that may have tipped the balance in causing a child to refuse to attend school. Illness or injury of a family member or of the child may be the initial reason for nonattendance. Similarly, the death of a relative or close friend may precipitate the refusal. Moving to a new home, community, or school also may contribute to refusal. The longer a child has been out of school, the more difficult and stressful returning can become.

### Clinical Management

In 1958, Eisenberg stated, "[I]t is essential that the paralyzing force of the school phobia on the child's whole life be recognized. The symptom itself serves to isolate him from normal experience and makes further psychological growth almost impossible. If we do no more than check this central symptom, we have nonetheless done a great deal." The foundations of any clinical treatment plan are rapport, trust, and respect. The initial interview should serve not only as a means of gathering data, but also as the start of a therapeutic alliance. Physicians should use a sensitive, holistic approach to data gathering, because the history-taking technique provides the first opportunity for creating a healing rapport. Factors related to the child, parents, family, and school environment must be investigated when exploring school maladaptation. An open mind that recognizes the unique and complex interactions of temperament, stressful life events, family systems function, learning style, parental medical or psychiatric conditions, and school system variables will be helpful in solving this problem. The child must understand that involving a physician in treatment reflects the seriousness of the symptoms and marks a turning point in changing the avoidant behavior.

Organic disease should be ruled out through a thorough history and physical examination, coupled with judicious laboratory evaluation. Time spent in conducting a thorough medical examination communicates the physician's sincere acceptance of the child's symptoms as being real. Parents are better able to confront the lack of organic disease when a physician who is completely familiar with the child's history and physical examination discusses the subject with them. A biopsychosocial approach from the outset also aids family acceptance of psychiatric concerns. The laboratory should be used in a symptom-specific, noninvasive, cost-effective manner consistent with ruling out possible organic disease. Additionally, addressing the potential contributions of parental disorders or specific environmental problems will be helpful in formulating a treatment plan.

The parents, physician, and school personnel must all agree that returning to school as quickly as possible is the immediate goal of treatment. Allowing the child to stay home while awaiting laboratory data results or using home tutors only delays the inevitable and makes the return to school more difficult. A specific plan must be developed to respond to clinical symptoms. Objective criteria for school absence, such as a measured fever, should be consistently used in modifying performance expectations, both at home and in school. Parents in doubt should seek the guidance of the child's physician regarding the significance of acute symptoms

before keeping the child home. In addition, the significant attachment figures in the child's life must make it clear they will adhere to the therapeutic program consistently and persistently. In most cases of school refusal, especially in the elementary years, the aforementioned program, carried out by the primary care pediatrician, is curative. Other treatment modalities, typically used by a mental health professional, include desensitization, psychotherapy, hypnotherapy, cognitive restructuring, and behavior modification. A variety of psychopharmacologic agents have been used to manage anxiety- or depression-based school refusal. Selective serotonin reuptake inhibitors (SSRIs) predominate the scant literature and have been found to be useful in some individuals. Concerns about a possible relationship between SSRIs and risk of suicide in children and adolescents have reduced the number of primary care physicians willing to prescribe these medications. Children who are recalcitrant to behavioral interventions may require referral to a mental health specialist. Suggested criteria for mental health referral are listed in Box 189-2.

Mental health professionals typically employ cognitive behavioral therapy with or without SSRIs. Severe cases may require inpatient treatment.

### Prognosis

Most children who refuse to attend school quickly overcome the difficulty with appropriate clinical management. Intermittent relapses associated with stress or new separation experiences, such as camp or sleepovers, occur in approximately 5% of children. Children who require psychiatric management do not fare as well. Most published series in the psychiatric literature reveal significant cohorts of patients requiring ongoing therapy and having persistent difficulties in emancipating themselves from their family. Phobias, depression, and anxiety are more common in adults who have a history of childhood school refusal. Table 189-1 lists long-term sequelae in children with school refusal.

### Prevention

Anticipatory guidance is an excellent means of primary prevention, and allows the primary care physician to advise parents on developmentally appropriate separation guidelines. For example, by the time an infant is 6 months of age, the parents should be able to spend some evenings out alone. By 1 year of age, peer contact should be encouraged. Toddlers should experience babysitters while awake. By age 3 years, the child should experience being away from home without a parent, such as in a playgroup or at a neighbor's home. Age 4 years is a good time to consider preschool for the child. Such guidance can be shared in the context of routine health supervision. Parents should also be discouraged from keeping children home because of minor illness, and physicians must avoid unnecessary medical restrictions.

Preventing vulnerable child syndrome is also important when caring for ill children. This disorder arises when parents think that their child's life has been threatened significantly, and it results in separation

### BOX 189-2 Criteria for Mental Health Referral

- Unresponsive to management
- Out of school for 2 months
- Onset in adolescence
- Psychosis
- Depression
- Panic reactions
- Parental inability to cooperate with treatment plan

**Table 189-1**

### Long-term Sequelae in Children With School Refusal

OUTCOME	PREVALENCE
Interrupted compulsory school	18%
Did not complete high school	45%
Adult psychiatric outpatient care	43%
Adult psychiatric inpatient care	6%
Criminal offense	6%
Still living with parents after 20-year follow-up	14%
Married at 20-year follow-up	41%

difficulties, overprotection, bodily concerns, and underachievement in school. Parents need to be informed about the true significance and prognosis of any medical difficulty the child has experienced. Physicians have a responsibility to avoid creating iatrogenic misconceptions about a child's health. They can accomplish this task by using everyday language as much as possible, rather than medical jargon, and by demystifying anxiety associated with insignificant findings, such as a functional murmur. Parents need to be reassured that children who have recovered fully from an acute illness are at no increased risk for future illness. By inquiring about children's school attendance and promoting healthy parenting styles, primary care physicians can help prevent school refusal.

### TRUANCY AND DROPPING OUT

Truancy is a good predictor of dropping out at a later date. Many schools in inner cities report daily absence rates above 20%, with most of this thought to be the result of truancy; an equal or greater percentage of inner-city school children never finish high school. Truancy is a serious social problem that can have lifelong consequences. Unemployment or underemployment, criminal behavior, marital problems, and

chronic social maladjustment are often seen in children with truancy or children who drop out. These same long-term outcomes have been identified in groups of children who have learning disabilities. One risk factor for truancy is learning disability and its associated school failure.

Truancy also has been noted among children who have a history of having been sexually abused. Other risk factors are low socioeconomic status, conduct disorder, gang membership, substance abuse, cigarette smoking, and family discord. Early recognition of children at risk should prompt immediate intervention to promote optimal adjustment. Mobilization of resources in the school, community, and family is critical to help prevent progression from truancy to dropping out. Creative programs to foster school attendance and success have been conducted with variable results. An emerging new truancy variant is the child who goes to school or its immediate environment but does not attend class. This child is participating in the social aspects of the school community but is shunning the academics. Medical physicians can assume an advocacy role in guiding and supporting therapeutic interventions in the educational and social welfare arenas.

## CONCLUSION

Absenteeism is a symptom that has multiple causes. Because success in school is often the foundation for continuing success in life, health care professionals must devote thoughtful attention to understanding and treating absentees. Using a biopsychosocial model and mobilizing multidisciplinary resources are the keys to clinical success.

## Chapter 190

# SCROTAL SWELLING AND PAIN

Lane S. Palmer, MD

Scrotal swelling can be particularly frightening for boys and their families, and because the differential diagnosis includes conditions that demand emergent treatment, it poses a challenge to pediatricians. A helpful organizing strategy during evaluation is to classify the scrotal swelling as either painful or painless and as acute or chronic (Box 190-1). Rapid and accurate evaluation of a boy with scrotal swelling depends on a thorough history and a physical examination of the genital area and abdomen that includes both inspection and palpation. Laboratory tests may be helpful but are not usually decisive, whereas imaging studies can be helpful in confirming a diagnosis and guiding management.

**BOX 190-1 Causes of Scrotal Swelling****ACUTE, PAINFUL SCROTAL SWELLING**

- Torsion of spermatic cord
- Torsion of appendix, testis, epididymis
- Acute epididymitis, orchitis
- Mumps orchitis
- Henoch-Schönlein purpura
- Trauma
- Insect bite
- Thrombosis of spermatic vein
- Fat necrosis
- Hernia
- Folliculitis
- Dermatitis, acute

**PAINLESS SCROTAL SWELLING**

- Tumor
- Idiopathic scrotal edema
- Hydrocele
- Henoch-Schönlein purpura
- Hernia

**CHRONIC SCROTAL SWELLING**

- Hydrocele
- Hernia
- Varicocele
- Spermatocele
- Sebaceous cyst
- Tumor

**EVALUATION OF THE CHILD WITH SCROTAL SWELLING**

The history should be taken from both the child (when possible) and the parent. The physician must determine whether the swelling or pain is a single event or recurrent and whether it is acute or chronic. The exact timing of the onset of symptoms is vital, particularly in the presence of acute pain and swelling. The nature of the pain must be determined: sharp, dull, constant, intermittent, constant with intermittent increases in intensity, or associated with nausea or vomiting. The location of the pain needs to be ascertained (ie, in the scrotum, specifically the testis; radiation into the abdomen or from the abdomen into the scrotum; laterality of the swelling and pain). Associated factors such as activity or positions that alleviate or aggravate the pain and swelling should be elicited. The nature of the swelling is important: specifically, whether the swelling changes in size during the course of a single day or whether it is constant or, in general, increasing or decreasing with time. Other important considerations include recent trauma, sexual activity, use of medications, the presence of rashes, weight loss, and nausea and vomiting.

The physical examination should include the abdomen, groin, and scrotum. Palpation of the abdomen and groin is important in determining whether an intraabdominal process is extending into the scrotum. Inspection of the scrotum should look for laterality of the process, scrotal erythema, and orientation of the testis, whereas palpation will determine the presence and symmetry of cremasteric reflexes, testicular position, tenderness, localization of the swelling to the intrascrotal contents, or the presence of proximal extension into the cord.

In general, laboratory tests are of limited value. The white blood cell count may be elevated in the setting of infection. Urinalysis may be helpful in distinguishing orchitis from torsion of the spermatic cord or testicular appendage when white blood cells or nitrites are present.

Imaging studies can be useful in differentiating among possible diagnoses. Ultrasound of the scrotum can be used to determine whether the scrotal swelling is fluid filled or solid, arising from the abdomen extending into the groin, limited to the scrotum, or arising from the testis or spermatic cord structures. Ultrasound with Doppler can assess the flow of blood into the testis, helping to differentiate torsion of the testis from an inflammatory process. Nuclear scintigraphy using technetium-99m pertechnetate is another way to evaluate blood flow to the testis; absence of flow results in a cold spot and suggests torsion, whereas inflammation results in increased flow to the same area. Nuclear scanning is less limited by the user variability associated with ultrasound and does not require placing a probe over a tender area. However, the study uses ionizing radiation and takes longer to perform than ultrasound, thus limiting its utility when time is of the essence. The sensitivity and specificity of the 2 modalities are similar.

**ACUTE SCROTAL SWELLING WITH PAIN**

The sudden onset of scrotal swelling and pain can be a surgical emergency and therefore warrants urgent evaluation and management. The primary clinical entities that constitute this constellation of signs and symptoms include torsion of the testicle, torsion of the testicular appendages, and epididymitis-orchitis (Figure 190-1).

**Torsion of the Testicle**

Testicular torsion is the twisting of the spermatic cord, with resulting compromise of the blood supply to the testis. This compromise and the risk it poses for testicular loss makes torsion a surgical emergency. In the neonate, the torsion occurs on the cord above the insertion of the tunica vaginalis (ie, extravaginal torsion). In the adolescent, the *bell clapper deformity* leads to torsion on the cord within the confines of the tunica vaginalis (ie, intravaginal torsion). Torsion of the spermatic cord first causes venous congestion, which is followed by compromise of arterial blood flow. Spermatogenesis may be compromised after 4 to 6 hours of ischemia. Similarly, testicular salvage is time dependent, with universal loss of the testis after

**Figure 190-1** Structures of the scrotum.

24 hours of torsion. A familial tendency has been described, and although the mode of inheritance remains ill-defined, 1 family with 3 generations has been identified. In addition, there may be some seasonal variation in the presentation of acute testicular torsion with a predilection for the colder months, although this has not been true in all series.

### **Incidence**

Testicular torsion occurs in 1 in 4,000 boys. Although a peak in incidence occurs in the neonatal period, testicular torsion more commonly occurs between the ages of 12 and 18 years. Nevertheless, testicular torsion should not be excluded from the differential diagnosis of acute scrotal swelling and pain based on age.

### **Evaluation**

The history typically describes acute onset of constant, severe scrotal pain aggravated by physical activity and sometimes alleviated by being still. If periods of acute respite from the pain occur, then intermittent torsion and detorsion should be considered. Nausea and vomiting may occur. The patient may have a history of incidental antecedent scrotal trauma, but the onset of pain usually occurs during periods of rest or sleep. Characteristic findings on physical examination include scrotal erythema and swelling of the involved hemiscrotum. Further inspection may reveal a higher-than-normal position of the testis within the scrotum and may also demonstrate a horizontal rather than the normal vertical orientation of the testicle. Evaluation of the cremasteric reflex should begin on the contralateral side, along with palpation of the apparently unaffected testis to confirm normal size and position. Unilateral loss of the cremasteric reflex on the side of the swelling and pain highly correlates with the

**Figure 190-2** Intraoperative photograph of nonsalvageable testis after prolonged period of pain.

presence of torsion. The testis should then be palpated despite the pain the maneuver may cause to help differentiate torsion from epididymitis. With torsion, exquisite pain is elicited on palpation from the testis, as well as from the epididymis and distal spermatic cord. In some instances, the actual point of torsion of the spermatic cord can be palpated. An associated hydrocele may be palpated and confirmed by transillumination. A tense or large hydrocele often makes the examination difficult. Urinalysis is unremarkable, and although the white blood cell count may be mildly elevated, it is not discriminating. Imaging by nuclear scintigraphy or Doppler ultrasound should be performed if the diagnosis of testicular torsion is in question, but only when it will not unduly delay surgical exploration if a torsion exists, adding to the risk for testicular loss. The absence of blood flow on Doppler and the presence of heterogeneous parenchyma are indicative of a “missed torsion” and a nonsalvageable testis.

### **Treatment**

Surgical intervention is not only indicated when testicular torsion is strongly suspected, but also should be considered in equivocal cases when torsion cannot be convincingly excluded. The likelihood of salvaging the testis, the goal of surgical exploration, is highest when surgery occurs shortly after the onset of pain; the chance for a successful outcome dissipates rapidly with time (Figure 190-2). With surgery, the affected testis is explored first, and when torsion is present, the cord is detorsed. The contralateral testis, which may have the same anatomic defect, is explored and fixed in place to avert a future metachronous torsion. The affected gonad is then reinspected and the possibility of salvage determined. If the testis can be saved, then it is fixed in the scrotum. Subsequent atrophy may still

result because of the vascular insult, and fertility may be compromised as well.

When testicular torsion is diagnosed, manual detorsion can be attempted while surgery is being arranged. The testis is twisted either clockwise or counterclockwise. When twisting in 1 direction has not succeeded, an attempt in the opposite direction can be made. When the procedure is successful, the return of blood flow to the testis provides rapid relief from pain. If manual detorsion can be accomplished preoperatively, then the surgical intervention to tack down the testes can be performed electively.

### Neonatal Testicular Torsion

Neonatal testicular torsion can exhibit at delivery as a nontender hard scrotal mass. Salvage in these cases is rare, and emergent exploration is futile. At exploration, the contralateral testis should be anchored and the nonviable testis removed. Although neonatal torsion can occur after delivery, this is very uncommon and then is more typical of torsion in the older patient, with a greater potential for salvage if intervention is rapid.

### Torsion of the Appendix Testis

#### Evaluation

Torsion of the appendix testis or appendix epididymis may lead to a clinical picture similar to that of the more consequential and urgent torsion of the spermatic cord. The appendix testis is a vestige of the Müllerian duct system and hangs from the anterior surface of the testis where it meets the head of the epididymis. When it torses, inflammation and swelling of the testis and epididymis ensues, causing testicular pain and scrotal erythema. The onset of pain and swelling is commonly acute but can be progressive, usually occurring during periods of rest. The pain can be severe, but nausea and vomiting are less common than with testicular torsion. The physical examination may demonstrate hemiscrotal erythema and swelling. The *blue dot sign*, with the necrotic appendage visible through the scrotal skin, can help make the diagnosis. A normal cremasteric reflex is present bilaterally, and the testis is normally positioned within the scrotum. Testicular discomfort, if present, is typically mild, but point tenderness may be elicited from the uppermost pole of the testis near the head of the epididymis—the location of the appendages. On palpation, the examiner may feel a 3- to 5-mm tender indurated mass on the upper pole. In some cases, the inflammatory process resulting from torsion of the appendage can lead to physical findings that make differentiating from true spermatic cord torsion impossible. In these cases, imaging may be helpful because either scrotal Doppler ultrasound or nuclear scintigraphy will demonstrate normal or increased flow to the ipsilateral testis.

#### Treatment

The management of the torted appendage is nonsurgical. The patient should rest and use nonsteroidal pain relievers and cold compresses for several days to reduce the inflammation, swelling, and pain. Surgical intervention is indicated only when the diagnosis of

acute testicular torsion cannot be excluded. In these cases, the infarcted appendage is removed at surgical exploration.

### Acute Epididymitis-Orchitis

#### Evaluation

Acute inflammation of the epididymis or testis occurs in both young and older boys. Uncommon in the younger child, it usually results from an anomaly of the urinary tract, either congenital or acquired, which can often be identified by renal and bladder sonography. Renal duplications and posterior urethral valves are among the more common anomalies. Traditionally, a voiding cystourethrogram has been a routine part of the evaluation, but its yield is low with a normal ultrasound and a sterile urine. In children who perform intermittent catheterization, epididymo-orchitis can occur from the retrograde passage of bacteria back from the ejaculatory ducts at the level of the prostate to the testis and epididymis.

In the older child and adolescent, the history and physical examination may help distinguish epididymitis or orchitis from testicular torsion or appendix torsion, but this is not always the case. The history can reveal an acute or more protracted onset of pain. The patient may have fever or dysuria. Epididymal inflammation may arise after scrotal trauma. In the adolescent patient, a history of sexual activity or a urethral discharge helps guide antibiotic treatment. The physical examination reveals scrotal erythema and swelling and an intact cremasteric reflex. Palpation during the early phase of the inflammatory process demonstrates tenderness limited to the epididymis, whereas in the later phase, the tenderness and inflammation include both the epididymis and testis, and the distinction between the 2 structures may be difficult to appreciate. The Prehn sign (relief of pain with testicular elevation) may be positive.

Laboratory and radiologic imaging are useful in these cases. Urinalysis may prove positive for white blood cells and nitrite but is often unremarkable among adolescents. The white blood cell count is usually elevated. Ultrasound and nuclear scintigraphy studies demonstrate either normal symmetrical blood flow or increased blood flow to an enlarged epididymis or testis.

#### Treatment

Management of epididymo-orchitis requires antibiotic therapy that is based on the results of the urine culture and sensitivities. In the sexually active adolescent, the choice of antibiotic coverage must also include coverage of gonococcal and nongonococcal sexually transmitted infections. Additionally, anti-inflammatory agents, scrotal elevation, and rest should be prescribed.

### Other Causes of Acute Swelling and Pain of the Scrotum

#### Henoch-Schönlein Purpura

Henoch-Schönlein purpura is a systemic vasculitis that can cause abdominal pain, joint pain, renal disease, and bleeding from the gastrointestinal tract

and may involve the scrotal wall in a minority of cases. The onset may be insidious or acute, producing a variable degree of erythema and edema. In more severe cases, the process may involve the testis and epididymis, mimicking testicular torsion. The presence of concurrent Henoch-Schönlein purpura and testicular torsion has been reported; therefore, if torsion is a consideration, then imaging with either Doppler ultrasound or nuclear scintigraphy is indicated to evaluate testicular blood flow. Surgical exploration may be needed in equivocal cases.

### Focal Fat Necrosis

Focal fat necrosis can result in scrotal pain and swelling, usually after trauma, in an obese boy. The examination demonstrates pain and swelling limited to the scrotum and not the testis; however, the examination can be limited by the discomfort and the degree of obesity. If properly diagnosed, then management consists of rest and anti-inflammatory agents. When spermatic cord torsion cannot be excluded clinically, either an imaging study or immediate surgical exploration is indicated.

### Trauma

Injuries can vary from zipper entrapment of scrotal skin to more severe blunt or straddle trauma affecting the scrotal contents. The history can be definitive. The physical examination must include both hemiscrotums and the surrounding structures (penis, perineum), assessing for swelling, ecchymosis, and bleeding. Palpation may be limited by the degree of swelling or blood within the scrotum. The tenderness may be limited to the testis or the epididymis, depending on the extent of the trauma. Scrotal ultrasound can document the integrity of the testis and of the tunica albuginea and the adequacy of blood flow. Testicular or spermatic cord contusions are managed symptomatically, whereas testicular rupture may require surgical exploration, evacuation of the hematoma, debridement, and repair (when possible); however, a nonsurgical approach has been reported.

### Mumps Orchitis

Mumps orchitis can occur at any age but is more common among adolescents. Rarely occurring in isolation, the pain and swelling usually occur within 1 week

after parotitis. The physical examination demonstrates a tender testis. Treatment is symptomatic. Infertility may occur when mumps orchitis results in atrophy of both testicles.

### Scrotal Skin Disease

Insect bites, folliculitis, and allergic dermatitis may cause erythema and edema of the scrotal wall. The history may be of limited utility. The examination reveals redness and edema limited to the scrotum, with a normal testicle and spermatic cord. Idiopathic scrotal edema affects children younger than 14 years, with acute erythema, edema, and mild scrotal wall tenderness, sparing the testis and cord. The process resolves spontaneously. The management includes rest and scrotal elevation.

## SCROTAL SWELLING WITHOUT PAIN

### Inguinal Hernias and Hydroceles

Hernias and hydroceles, the most common causes of scrotal swelling, fall along a continuum (Figure 190-3). They are more common in premature infants and are predominately right sided. Most inguinal hernias and hydroceles are caused by persistent patency of the processus vaginalis (PPV), a peritoneal evagination that accompanies the testis during its abdominal-scrotal descent. The layers of the processus vaginalis condense late in gestation or early postnatally. Obliteration of the processus vaginalis only around the testis leads to an indirect inguinal hernia with the protrusion of fluid (or other contents) through the internal ring to the end of the pouch and potentially to the scrotum. A communicating hydrocele occurs when fluid travels through a PPV into the tunica vaginalis around the testis. A scrotal hydrocele occurs after complete obliteration proximally with patency distally. Hydroceles of the cord occur when the processus vaginalis obliterates proximally and distally, leaving a patent area in the midportion with retained fluid.

Inguinal hernias and hydroceles may be asymptomatic or may have a spectrum of symptoms. A hernia can occur at any age as an inguinal swelling extending toward and potentially reaching the scrotum. The swelling expands with increases in intraabdominal pressure (eg, crying, bowel movements, coughing, exercise). The parent or child will often report the

**Figure 190-3** Diagram of the continuum of hernia and hydrocele.

swelling to be smallest in the morning and greatest later in the day. When omentum is in the hernia sac, the likelihood of spontaneous reduction is low, and periods of discomfort can occur. An incarcerated hernia can produce pain, fever, nausea, vomiting, and irritability. A hydrocele is usually an asymptomatic bulge in the scrotum. In many instances, whether the hydrocele is acute or whether the scrotum has been chronically enlarged is unclear. The patient may have a history of trauma to the scrotum that stimulates the production of serous fluid. When the scrotum changes sizes during the day, the physician should suspect a communicating hydrocele.

### Evaluation

The physical examination is often sufficient to distinguish among these entities. The examiner should feel for the testis first and keep it in mind during the rest of the examination so as to avoid confusing it with the contents of an incarcerated hernia. A bulge in the inguinal region with fluid that can be gently reduced back into the abdomen is diagnostic of an inguinal hernia. In the cooperative child who can increase his intraabdominal pressure, this procedure may be repeatedly demonstrated particularly with the child standing. When the fluid is limited to the testis and the spermatic cord can be palpated above the fluid, a hydrocele is present. The presence of a thickened spermatic cord or a *silk stocking sign* (the feel of the layers of the processus vaginalis being rubbed against each other) is suggestive of a PPV or a hernia, which is helpful in distinguishing a scrotal hydrocele from a communicating hydrocele. Hydroceles transilluminate, but so can the incarcerated bowel of an infant. A hydrocele of the spermatic cord feels distinct from the testis and is round or ovoid, possibly mimicking the presence of an additional testis. Hydroceles, whether communicating, scrotal, or of the cord, are rarely associated with tenderness on palpation.

Ultrasound can be useful to delineate the scrotal contents, especially when a large or tense hydrocele limits the physical examination, and to determine the cystic or solid nature of a tense scrotal mass (eg, hydrocele, tumor) or spermatic cord mass (eg, hydrocele of the cord, paratesticular tumor). Laboratory tests are useful only in cases of incarcerated inguinal hernias, with an elevated white blood cell count and possible acidosis.

### Treatment

Inguinal hernias and communicating hydroceles should be repaired on diagnosis to prevent incarceration. The risk for incarceration increases with time and is more likely in the young child or infant. Communicating hydroceles should also be repaired on diagnosis to avert progression. Surgery is performed inguinally, during which the sac is isolated from the cord structures and ligated at the level of the internal ring. The likelihood of a PPV on the contralateral side is highest in younger children, and the need for contralateral exploration remains controversial. However, diagnostic laparoscopy through the isolated ipsilateral sac allows visualization of the contralateral ring (Figure 190-4). If the internal ring is open, then

**Figure 190-4** Laparoscopic appearance of a closed (*top*) and an open (*bottom*) internal inguinal ring. The ring appears at junction of the vas deferens and the internal spermatic vessels.

contralateral surgical correction proceeds. Most hydroceles resolve spontaneously by 1 year and should be repaired if they persist beyond this age. However, if the hydrocele is painful, tense, and large, then surgery should proceed sooner. In younger children, the surgical approach is inguinal; in older boys and adolescents, a scrotal approach is appropriate.

### Tumors

Testicular tumors are uncommon in children, accounting for 1% to 2% of all solid tumors, but occur in all

age groups. Fortunately, about 74% of prepubertal testis tumors are benign. Tumors are usually displayed as a hard, painless (or a vague, heavy-feeling) mass in the testicle detected by the child, parent, or examining physician. On palpation, the mass is harder than the substance of the testis, but this distinction may be difficult to discern. The mass may bulge from the surface of the testis. Tumors do not transilluminate. Scrotal ultrasound is used to delineate the mass and in some cases help to assess whether the mass is likely to be benign (anechoic). Preoperative tumor markers ( $\alpha$ -fetoprotein [AFP],  $\beta$ -human chorionic gonadotropin) should be drawn and used for postoperative monitoring. AFP cannot be used effectively as a tumor marker until it is no longer produced at about 8 months of age. Staging depends on serum markers, computed tomography (CT) imaging of the retroperitoneum and chest, and pathology. The surgical approach depends on the nature of the mass. All cases are approached through an inguinal incision in case the mass is malignant. Mature teratoma, the most common testis tumor among prepubertal males, is benign and is managed by testis-sparing surgery. Immature teratoma has also been successfully managed without removing the testis. Yolk sac tumor is the second most common tumor and presents with elevated AFP levels (recall caveat above). Radical orchiectomy is curative in more than 90% of cases (stage 1); platinum-based chemotherapy and possible retroperitoneal lymph node dissection may be needed for higher stage disease. Boys with Leydig cell tumors present with a solid testis mass and precocious puberty and can be treated with tumor enucleation. Gonadoblastoma occurs in dysgenetic gonads of children with disorders of sexual differentiation carrying a Y chromosome.

### Varicoceles

Varicoceles, which are dilations of the spermatic veins or pampiniform plexus, are present in 15% of male adolescents and adults and may have a negative impact on fertility. The dilated veins are usually asymptomatic and are detected either by the patient or by the physician during routine physical examination, usually between 10 and 15 years of age. On occasion, the patient may report some heaviness or a *dragging* feeling in the scrotum. A predilection for the left side exists, reflecting the anatomy of the left gonadal vein entering the left renal vein at a right angle. The right gonadal vein enters the vena cava directly at an angle, precluding reflux of venous blood. The presence of bilateral or right-sided varicoceles warrants an abdominal and pelvic ultrasound or CT scan to evaluate for a possible mass occluding venous return. Physical examination should be performed with the patient in the supine and standing positions; the varicocele is usually decompressed in the supine position and present in the standing position. Inspection may reveal the classic *bag of worms* of dilated veins (grade 3 of 3). In other cases, increased blood pooling in the veins can be prompted by a Valsalva maneuver (grade 2 of 3). Less commonly, a varicocele is detected only by ultrasound (grade 1 of 3). Testicular size, most accurately assessed by ultrasound, should be measured; a significant loss of testicular volume is one indication for

surgery. Other indications for repair include abnormal semen analysis (older adolescent patients), very large varicoceles, and pain. Corrective measures include open surgery, laparoscopic surgery, or radiologic ablative techniques—all aimed at occluding direct venous return through the internal spermatic vein to improve the likelihood of normal fertility. In most cases, the testis will subsequently increase in size to equal that of the contralateral testis.

### Spermatoceles and Epididymal Cysts

Spermatoceles and epididymal cysts represent sperm-filled cystic lesions attached to the upper pole of the testis. They are separate from the testis and can be transilluminated. Painless and round, they usually remain stable in size but can sometimes enlarge. Management consists typically of observation, but surgery may be indicated when pain or significant enlargement is present. Postoperative scarring can obstruct the epididymal ductal system and lead to infertility.

## Chapter 191

# SELF-HARM

Nancy Heath, PhD; Jessica R. Toste, PhD; Timothy R. Moore, PhD;  
Frank Symons, PhD

## FOUNDATIONS OF SELF-INJURY

Self-injury in children and youth may be grouped into 2 classifications: self-injury with intent to die (suicidal behaviors) and self-injury without intent to die (nonsuicidal self-injurious behaviors). Two of the best-known behaviors within the nonsuicidal classification are *nonsuicidal self-injury* (NSSI), occurring in typically developing children and youth, and *self-injurious behavior* (SIB), most common among children and youth with intellectual and developmental disabilities. Although cases of NSSI are seen more commonly than SIB in clinical practice, SIB is generally the more severe behavior. However, both forms of self-injury pose significant challenges to pediatricians. The chapter describes the independent and converging characteristics and features of each of these presentations of self-injury.

### Definition and Types of Self-injury

Nonsuicidal self-injury refers to the deliberate destruction of one's own body tissue, occurring without suicidal intent and for purposes not socially sanctioned. Thus, NSSI excludes piercings and tattoos. Most commonly, NSSI includes superficial to moderate self-cutting, burning, scratching, and bruising. NSSI occurs among typically developing children and adolescents. This behavior is often engaged in repetitively over long periods of time, with increasing severity, and has been found to be a significant risk factor for future suicidal behaviors. Furthermore, these self-inflicted injuries can result in medical complications, infection, or permanent scarring. Historically, this behavior has also been referred to as *self-mutilation*, *self-harm*, and *parasuicide*. The definition of NSSI excludes extreme forms of body mutilation (eg, amputation, enucleation) seen in patients with psychosis, as well as stereotypical self-injury seen among individuals with intellectual and developmental disabilities (IDD).

SIB among children and youth with IDD shares a similar definition with NSSI. SIB is defined as physical acts directed to one's own body that result in or produce tissue damage, or have the possibility of producing tissue damage if left unchecked. However, the most common forms of SIB are different from those of NSSI, and may include head banging, biting, scratching, pinching, and rubbing. Chronic SIB poses tremendous challenges for affected individuals and their families. Indeed, SIB is among the most disturbing and serious of all behaviors exhibited by children with IDD, because it has profound implications for a child's health and quality of life. SIB often leads to increased risk for institutionalization and social stigmatization, and decreased opportunities to learn.

### Epidemiology

The onset of NSSI most commonly occurs in early adolescence (12–14 years), although it is increasingly common for this behavior to occur among prepubertal children. Research has found that between 14% and 20% of adolescents in community samples report having engaged in NSSI at least once during their lifetime. Studies of mental health issues in college students have reported comparable lifetime prevalence estimates, suggesting that rates of NSSI are similar from adolescence to young adulthood. Currently, there has been no research investigating the prevalence of NSSI among prepubertal children in the general population; however, there is a clear indication from retrospective reports of self-injurers, as well as anecdotal reports (eg, physicians, school professionals) that NSSI does occur among children. In contrast to studies conducted with community samples, lifetime prevalence estimates of NSSI among clinical adolescent samples are substantially higher, with rates ranging from 60% to 80%.

Interestingly, while research has found NSSI rates to be much higher among females in clinical settings, the same pattern is not consistently found in community samples. Some studies have found a female predominance in the behavior, while others conclude that there may be little or no gender difference in occurrence of NSSI. In a review of the literature of NSSI among adolescents, Heath and colleagues found that studies reporting gender differences have included overdose and medication abuse, which have been found to be largely female behaviors. Investigations that are limited to cutting, burning, self-hitting to bruise, and other forms of tissue damage have failed to find a gender difference. Thus, it is important to avoid the assumption that NSSI is a predominantly female behavior in community practice, even though girls are more likely to be seen in clinical settings.

Findings regarding age of onset and gender patterns for SIB are notably different from those for NSSI. SIB occurs at all levels of IDD across the lifespan, with greater frequency typically reported among children with more severe intellectual impairments. The specific age of onset is typically unknown, but reports documenting SIB have included children as young as 18 months. Epidemiologic estimates vary depending on study design and participant characteristics, but it is estimated that approximately 20% of individuals with IDD living in large aggregate care facilities exhibit some form of self-injury. Unlike NSSI, there are clear gender differences in occurrence of SIB, with males overrepresented by a ratio of approximately 4 to 1. There have been no studies directly addressing ethnic differences in the prevalence of NSSI or SIB among children with IDD.

### Etiology and Function

For many years, self-injury occurring outside of the IDD population was believed to be indicative of severe psychiatric disorders, particularly borderline personality disorder (BPD). However, emerging research has shown that NSSI is not limited to individuals with BPD. Research has revealed that this behavior serves

a number of different functions. These may be understood as falling into 2 broad categories: functions that serve an internal or automatic purpose (eg, to elicit a calm feeling or eliminate tension) or functions that serve an external or social purpose (eg, as a form of communication or to elicit a response). For most individuals who engage in NSSI, emotion regulation difficulties are at the root of this behavior. These youth experience their intense negative emotions as intolerable and use NSSI to gain relief.

Although use of NSSI to regulate internal states or emotions has received the most support in the literature, for a minority of youth it seems that social factors may also play a role in this behavior. It has been suggested that in these cases NSSI serves as a form of communication to parents and peers when alternative forms of communication are perceived as being ineffective. Thus, for typically developing youth, the primary function of the behavior is to obtain relief from an internal state or experience. In contrast, as discussed below, SIB among children and youth with IDD is most often found to serve an environmental or social function (eg, to gain attention from others or to escape from task demands); however, it is recognized that an automatic function may also be involved in many cases (eg, to attain relief from pain caused by an underlying medical condition).

Advances in behavioral assessment technology have led to remarkable progress in identifying environmental and biologic variables underlying SIB. While the etiology of SIB may be related to an undiagnosed painful medical condition in some cases, the specific etiology of SIB is unknown in most cases. Little is known about the behavioral or biologic mechanisms influencing the early development of SIB in young children with IDD. Communication impairment associated with IDD is a primary risk factor, as is the overall severity of the intellectual impairment.

### Co-occurring Disorders

Research on co-occurrence is crucial for knowing how to assess and treat youth who engage in different forms of self-injury. For example, because the underlying functions of NSSI are similar to those of other mental health issues, it is necessary to be aware of which conditions tend to occur with NSSI and how to effectively assess and monitor them. Some of the most commonly co-occurring disorders include mood disorder, anxiety disorder, impulse control/conduct problems, uncontrolled anger, BPD, alcohol or substance abuse, eating disorders, and suicidality.

Similarly, a number of IDD-related syndromes tend to occur with SIB. The most common of these include Lesch-Nyhan syndrome, fragile X syndrome, Cornelia deLange syndrome, Prader-Willi syndrome, and Rett syndrome. Whether there are mechanisms specific to any single genetic disorder and the expression of SIB is unclear but unlikely.

## EVALUATION

Diagnostic and treatment approaches to NSSI and SIB differ substantially. NSSI is largely hidden and may

range in severity or treatment needs; therefore, much of the focus for the physician is on early risk assessment and referral to appropriate treatment. In contrast, SIB necessitates an initial ruling out of a possible underlying medical condition followed by the need for a full behavioral evaluation by a behavior analyst certified by the Behavior Analyst Certification Board (BACB.com). Interestingly, despite the obvious differences between the diagnostic approaches to NSSI and SIB, both share the difficulty of preconceived notions regarding the behavior (based on common misconceptions) and the lack of consideration of both internal and external functions. For clarity, the following section is divided into separate, brief reviews of NSSI and SIB.

### Nonsuicidal Self-injury Signs and Symptoms

A particularly challenging aspect of NSSI among children and youth is that it is a largely hidden behavior. Most youth engaging in the behavior make great efforts to keep the behavior secret, perhaps revealing only to friends or peers in online communities. Despite the child's reluctance to reveal the behavior, physical examination of the child will reveal fresh injuries, scars, burns, or unexplained bruises that are clearly indicative of NSSI. Some individuals will limit themselves to pin or razor blade scratching that they may explain as "cat scratches." Awareness of NSSI in typically developing youth ensures that physicians are cautious in their interpretation of signs of injury (eg, bruising, burning, or cutting) as signs of physical abuse (intentional harm by another).

One of the most significant obstacles to identification of NSSI by physicians is a lack of awareness of this behavior. It is widely thought that self-injury is largely a female behavior and limited to self-cutting; thus, NSSI is often overlooked in males or when other methods of injury are involved. Rather than understanding the underlying emotion regulation or "coping" function, physicians who encounter cases of NSSI often misidentify it as a suicide attempt or physical abuse, or assume that there are underlying disorders (eg, BPD, eating disorders). Additionally, physicians must recognize the high rate of occurrence for NSSI in youth and that the behavior is not limited to specific social cliques (eg, "emos" or "goths").

### Diagnostic Approach

Of particular importance is the need to distinguish between NSSI and suicidal behaviors. In the past, researchers have often failed to distinguish between self-injury with and without suicidal intent. However, suicide attempts and NSSI are distinct behaviors and should be understood, managed, and treated differently. Suicide attempts are behaviors that may or may not result in injury, for which there is intent to die. In contrast, NSSI is a behavior in which immediate tissue damage is present, but for which there is no intent to die. In essence, suicidal behaviors express a wish to stop living, whereas NSSI is reported by the youth as an attempt to feel better without any conscious desire to die. Nevertheless, these behaviors are not mutually

exclusive, and some youth engage in both, albeit at different times and with different intents. Therefore, it is important to evaluate for both suicidal and nonsuicidal self-injury.

### **Risk Assessment and Effective Referral**

A key role of the pediatrician is to complete a risk assessment to determine the current risk level and make appropriate referrals. Assessment includes evaluation of risk for suicide, physical injury, and the presence of other co-occurring risk factors. In determining risk-level status, the physician must recognize that there is no simple formula for determining whether a youth is at high or low risk. Nevertheless, if there is increased risk for suicide or physical injury, or if there are significant mental health concerns, then the risk-level status of the patient increases. Despite the extensive list of factors contributing to risk stratification, many patients who self-injure remain in the low-risk category. These patients may have mild, nonclinical levels of depression, anxiety, negative body image, or self-derogation and may seem to be functioning extremely well academically, socially, and within their home environment. Despite this apparent positive presentation, research has found that engaging in NSSI (even if only a few times) indicates problematic emotional regulation and a need for intervention to develop more adaptive coping strategies. Furthermore, it is known that risk level for suicide by individuals who engage in NSSI is substantial and subject to change over time; thus, regular reassessment is essential.

### **Self-injurious Behavior**

#### **Signs and Symptoms**

The physician should be aware that SIB injuries can have pattern-mark appearances and can be mistaken for physical abuse. Children with developmental disabilities, however, may be at higher risk for abuse or neglect. Careful history, risk assessment, and physical examination are warranted.

Presence of SIB often includes biting of the hands, arms, or lips; banging the head on solid surfaces; hitting the head or face with a closed fist or open palm; eye-poking; or scratching, picking, pinching, or rubbing skin. Mild, moderate, or permanent tissue damage and disfigurement, possibly life threatening, can occur if SIB is left untreated.

#### **Diagnostic Approach**

Behavioral evaluation of SIB is predicated on 3 empirically based assumptions: (1) SIB is functional, learned behavior (ie, a function, in part, of its circumstances and consequences); (2) the momentary likelihood of SIB is influenced by antecedent stimulus conditions (ie, it occurs more often in the presence of certain people, places, materials, demand contexts, and biological states than in others); (3) intervention linked to function (ie, related to antecedents and consequences) rather than form alone will result in superior, clinically significant outcomes. Behavioral evaluations require effort, time, and trained staff to administer and interpret, but lead to effective interventions more quickly than alternatives not based on behavioral function.

### **Functional Assessment and Analysis of Behavior**

Physicians who eliminate the possibility of underlying medical conditions and determine that SIB warrants evaluation should refer the patient to a board-certified behavior analyst (BCBA). State-by-state and provincial listings of BCBAs are available. Two broad categories of clinical evaluation procedures are available: functional assessment and functional analysis. Both types of evaluations are designed to generate information about environmental antecedents to, and contingent consequences of, behavior that can be directly linked to interventions. Functional assessments generate descriptive accounts of contextual and antecedent precursors to behavior as well as outcomes produced by behavior. The functional assessment interview is typically administered face to face, and it can be completed in approximately 1 hour (shorter or longer depending on the complexity of the behavior and level of information desired). The Questions About Behavioral Function, Functional Analysis Screening Tool, and Motivation Assessment Scale are more time-efficient survey forms that can be completed by caregivers at home or school. It is best practice to corroborate any interview and survey information with observations of the behavior, because these instruments have been found to generate different hypotheses about the function of SIB than observational accounts such as experimental functional analysis. Nevertheless, strong hypotheses of the function of SIB can be generated by these types of descriptive functional assessments and effective interventions can be developed based on those hypotheses.

Experimental functional analysis involves systematic manipulation of the antecedents to, and consequences for, SIB, and direct observation of the effects of these consequences. Typically, children are evaluated in clinical settings and the occurrence of SIB is compared across test and control conditions to determine whether SIB is sensitive to social consequences. The usual consequences evaluated are possible positive and negative reinforcers in the form of attention from others, escape from task demands, access to tangible items, or other preferred situations. When the presentations of antecedent and consequence stimuli are arranged systematically in a single-subject experimental design, causal claims between SIB and its consequences can be made. Experimental functional analysis requires highly trained professionals to administer and interpret (and is therefore more costly), but the tradeoff is confirmation of the environment-behavior relationship responsible for the maintenance of SIB, resulting in more prompt implementation of the proper intervention.

### **MANAGEMENT AND TREATMENT**

Effective treatment of NSSI begins with appropriate assessment. This includes a full history of the behavior, including age of onset; incidence over time; and specific aspects of the behavior over time, including the history of method(s), frequency, location(s), number of injuries per episode, and medical severity of injuries. These variables may change with time,

indicating an overall profile of increasing severity or a pattern of waxing and waning reflective of periods of stress. Currently, the only treatment approach for NSSI that has some empirical support (including randomized controlled trials) is dialectical behavior therapy (DBT) which has been found to be effective both with adults and adolescents. However, none of these studies used community samples of youth engaging only in NSSI; rather, this approach has been found to be effective with individuals with severe NSSI and co-occurring suicidal behaviors. DBT focuses on specific treatment goals arranged in a hierarchy of importance as follows: (a) decreasing life-threatening and NSSI behaviors; (b) eliminating behaviors that interfere with therapy; (c) decreasing behaviors that interfere with quality of life (eg, substance abuse, high-risk sex); and (d) skills training in mindfulness, distress tolerance, emotion regulation, and interpersonal effectiveness to help manage psychological distress. This approach is intensive and demanding of resources, requiring a therapist trained in DBT. Although DBT has been referred to as the “gold standard” of treatment, less intensive treatment approaches that incorporate the key elements of mindfulness, distress tolerance, emotion regulation, and interpersonal skills to some degree may be effective with community samples of youth who engage in NSSI. Regardless, at a minimum the physician working with the youth must be aware of the elements of DBT.

A child with IDD presenting with SIB should be evaluated for any possible illness or the likelihood of an acute or chronic condition that may be painful. Treating the underlying medical condition may lead to reduced SIB. For behavioral assessment, referral to a qualified specialist (eg, BCBA) is recommended. The evidence for SIB treatment based on behavioral evaluation is large and growing. Best practice calls for linking behavioral evaluation results directly to intervention strategies that include modifications to the antecedent environment in order to limit the presence of variables known to be associated with the onset of self-injury, and approaches to decreasing self-injury that emphasize reinforcement of desired behavior and de-emphasize the use of punishment. Specifics of any treatment regimen should be individualized with respect to the patient’s preferences, strengths, needs, and scope of SIB, as well as consideration of the caregivers’ preferences, strengths, capacities, and available family and community supports. Studies of neurobiologic factors associated with SIB have identified a role for opioidergic, dopaminergic, and serotonergic systems in the pathophysiology of SIB. These findings are in line with the results of a growing body of controlled psychopharmacologic studies demonstrating that SIB can be reduced to different degrees by agents that have actions in these neurochemical systems. One main difficulty to date is that it is not clear who will respond to what medication under what circumstances.

### Ongoing Care

The main consideration in the ongoing care of patients who have engaged in NSSI is the need for regular follow-up and suicide risk assessment. Although

many individuals will stop and not resume the behavior (exact numbers are unclear at this time), some youth will relapse and show a sharp escalation in severity following a stressor. While the prognosis is excellent for most youth who engage in NSSI at a low or moderate severity level, as a group they remain at significantly greater risk for suicide. Similarly, while tremendous advances have been made in the past 3 decades in our understanding and treatment of SIB, there is little evidence that the scientific community has effectively reduced the long-term burden of SIB on families and society. Prevalence estimates continue to suggest approximately 20% of people with IDD exhibit SIB, suggesting an ongoing need for intensive intervention with an emphasis on sustainability by incumbent supports.

### Self-injury Similarities and Differences

In summary, self-injury is generally understood to be a completely different phenomenon in typically vs atypically developing children and youth. While there are many differences in presentation and treatment approaches, these behaviors can be understood as possibly serving either an automatic or social function in both populations. Furthermore, it is essential in both instances to evaluate for the underlying functions in order to understand the reinforcers of these behaviors. Treatment for NSSI and SIB requires a detailed analysis and understanding of what is reinforcing the behavior and ultimately trying to interrupt this reinforcement chain. Effectively disrupting the response-reinforcer contingency depends, in part, on recognizing that self-injury elicits reactions from individuals in the patient’s or individual’s environment, which can create a complex situation (ie, it is a natural response on the part of a physician to want to react and stop an individual from harming himself). Documentation and clear communication to share information about any planned intervention is essential to effective outcomes.

#### WHEN TO REFER

##### NSSI

- Following initial risk assessment
- Emotional regulation difficulties or poor coping strategies

#### WHEN TO ADMIT

##### NSSI

- Threat of suicide
- Serious physical injury
- Underlying psychiatric conditions

## Chapter 192

# SELF-STIMULATING BEHAVIORS

Richard M. Sarles, MD; Sarah Edwards, DO

Repetitive and self-stimulating behaviors, such as head banging, head rolling, rocking, thumb sucking, and masturbation, as well as habits such as hair pulling and nail biting, are of concern to both parents and pediatricians. Research has suggested that commonalities exist among repetitive behaviors, sometimes classified as *stereotypies*, and that they represent an interaction of the stage of neuromotor development with environmental influences (eg, restrictive car seats and cribs) and are a homeostatic mechanism that serves to regulate stimulation from the environment. Many of these behaviors, such as head banging, head rolling, and rocking, typically appear before 12 months of age, peak soon thereafter, and subsequently decline rapidly. Thumb sucking (25%) and nail biting (23%) are the most common behaviors described in preschool children, with only 4% developing motor stereotypies. Young children practice self-stimulation through

thumb sucking and genital play, with a peak at age 2½ years. In general, most of these behaviors are self-limited to the preschool period and are usually viewed as normal, common, and expected behaviors. These habits generally do not signify psychological maladjustment. They often require little intervention other than reassuring the parents and suggesting adequate interaction with their child.

**HEAD BANGING AND ROCKING**

*Head banging* consists of rhythmic movements of the head against a solid object, such as the crib mattress or headboard, and is often associated with rocking the head and the entire body. It is observed most commonly at bedtime or at times of fatigue or stress and may vary in duration from several minutes to hours. Head banging often continues even when the child is asleep. The age of onset shows wide variability, but the behavior is witnessed most commonly during the preschool years. The reported incidence of head-banging or rocking behavior varies between 3% and 20%, with a male-to-female ratio of approximately 3:1. Occasionally a family history of such behavior can be found, but only 20% of siblings of children who rock exhibit similar or other rhythmic pattern disturbances.

Various theories have been developed to understand these self-limited but often disturbing behaviors. Rocking is thought to be a soothing, pleasurable experience that every infant encounters in utero and that most infants encounter from the neonatal period onward. The pleasure from movement is repeated throughout life, from being rocked in the mother's arms during early childhood, for example, to jumping rope and playing on swings in childhood, to dancing in adulthood. Individual constitutional patterns in childhood account for a wide variability in the amount of stimulation any particular child may require. However, in certain children, such as those who are hearing or sight impaired, emotionally disturbed, or severely intellectually disabled, marked rhythmic movements are commonly found. In these cases the movements may represent a compensatory reaction for a lack of stimuli or the inability to integrate stimuli. Head banging in children with severe disabilities can be a form of functional communication. For example, a child may increase head banging to receive parental attention or to avoid task demands. In addition, the child who has no disability but who is inactive because of physical illness generally shows a need for motor release that is often characterized by bed rocking or other rhythmic body movements, which generally disappear once normal mobility is restored.

Physical and neurologic examinations show these children to be predominantly within normal limits, and electroencephalogram studies are not indicated because the findings are generally not helpful. These behaviors seem to be linked to maturational patterns and correlate closely with teething and other transitions of growth and development, perhaps as a mechanism for increasing or reducing arousal and maintaining homeostasis. Even though psychosocial growth and development are apparently not disturbed

in these children and studies indicate no connection between rocking behavior and parental divorce or separation, the question of inadequate stimulation for the child should be raised, and the presence of family turmoil and stress should be investigated.

Treatment is generally directed toward assuring the parents that head banging cannot cause brain injury and that the child will show no adverse neurologic effects in later life; children who engage in head-banging behavior usually grow up as typical, coordinated children. Securing the crib to prevent rolling may help during the limited rocking behavior, but crib bumpers are not recommended because of concerns of suffocation, strangulation, or entrapment. Sedation in the form of diphenhydramine may prove effective, but psychotropic medication is generally unnecessary and is thus discouraged. Parents should not visit the child frequently at night, because doing so could reinforce what may become an attention-seeking behavior. Rarely, if ever, do fractures of the skull or cerebral hemorrhages result from head banging in typically developing children, but soft-tissue swelling and scalp contusions have been reported. Intracranial injuries and retinal detachment have been reported in children with autism and severe intellectual disabilities, and a protective helmet may be advised in severe cases. Consultation with a child psychiatrist or psychologist is indicated if the head-banging or rocking behavior persists beyond 3 years of age. For children who show a lack of social interaction or a preoccupation with themselves or with self-stimulatory behavior, consultation is indicated.

### THUMB SUCKING AND NAIL BITING

Thumb sucking occurs almost universally in infancy but varies among cultures. Infants may place virtually every object they encounter in their mouth unless parents, for safety reasons, restrict the object choice.

The pleasurable sensations associated with the double tactile experience of sucking and being sucked and the feelings of security and comfort that these experiences evoke tend to reinforce this behavior. Many families substitute artificial pacifiers as a more socially acceptable means of oral pleasure, and children themselves often spontaneously suck a security blanket, a doll, or a stuffed animal. Thumb sucking usually occurs during times of stress or boredom and at bedtime. Young children may suck their thumb to help themselves fall asleep. Social and family pressures generally limit thumb sucking to the preschool years. However, the habit may persist into adolescence. Approximately 25% to 40% of American children engage in finger sucking during the preschool years and 10% to 20% continue beyond 6 years of age.

Nail biting is an extension or permutation of the habit of thumb sucking. Some experts consider this behavior a form of more overt self-aggression; others would define nail biting simply as a variation of thumb sucking because this behavior is also seen typically during times of stress. An estimated 25% of preschoolers and 33% of children ages 7 to 10 years bite their nails. Adolescent rates of nail biting are as high as 45%. Thus nail biting, in contrast to thumb sucking, often continues throughout development, but

decreases to adult rates of 10%. Gender differences do not appear until adolescence when the incidence of nail biting is greater for males. A family history exists in most cases, but this habit is so common that such an apparent association may be of no significance. Children from higher socioeconomic groups and higher levels of parental education seem to demonstrate oral habits more often, but no clear correlation has been found with the number of children in the family, birth order, type of feeding, or feeding schedule.

Thumb sucking, nail biting, and cuticle biting or picking may be harmful to dentition and increase the risk of dental malocclusion and the incidence of digital cutaneous infections. There is a higher probability of malocclusion if thumb sucking continues after the eruption of permanent teeth. In addition, thumb sucking that persists into school age can bring on teasing from peers and criticism from teachers and family, leaving the child with decreased self-esteem and increased psychological distress.

Clarifying with parents the nature of these habits is important, as is encouraging them to avoid punishing or shaming the child for them. An underlying cause of tension should always be investigated, but simple behavioral therapy (based on positive reinforcement) is often sufficient to alleviate the habit. The parents should be advised to avoid punishment, threats, or anger. Encouragement in the place of restrictions is helpful in engaging children in their own program to decrease or eliminate the behavior.

Bitter-tasting commercial preparations applied to the fingers may be used as a reminder for the child, but these preparations are generally inadequate unless supplemented by consistent positive reinforcement. The choice of reinforcement reward should be the child's and might take the form of extra television privileges, dessert, or other special treats. A combination of aversive taste treatment and a reward system seems to be effective in treating chronic thumb sucking. Weekly visits to the physician for the first month of treatment are important to reinforce the change in behavior. Hypnosis is another treatment that is often successful and poses no danger; psychotropic medications, on the other hand, are of little value. If these habits are linked to other signs of emotional distress or if there is excessive nail biting and cuticle picking, referral to a specialist in behavioral disorders is warranted to investigate other mental health issues such as anxiety or a body-focused repetitive behavior disorder.

### MASTURBATION

Childhood masturbation is almost universal and often causes great parental concern. Genital exploration and touch typically begin around 2 months of age and evolve into masturbatory activities that peak at 4 to 5 years of age and again in adolescence. Such activity may vary from direct manual genital stimulation to movements of the thighs against each other. Rhythmic swaying or thrusting motions of the child while straddling a hobby horse, pillow, stuffed animal, or other objects also are common methods of masturbation. Infants and children are capable of a physiologic orgasmic response similar to that experienced by the

adult, except for the absence of ejaculation in the male child, as demonstrated by the common practice in Europe in the late 1800s of masturbating an irritable child to induce relaxation and sleep. Occasionally, this orgasmic response has been incorrectly thought to represent a convulsive or movement disorder in infants and children leading to unnecessary and expensive neurological workup. Masturbatory activity is generally initiated as a response to the learned pleasure associated with touching of the genitalia that is first experienced in infancy during normal body exploration. Masturbation will continue as a lifelong pleasurable experience unless suppressed by parents or other adults.

The physician needs to educate parents about healthy childhood sexual development. Physicians should counsel parents on masturbatory practices and emphasize that masturbation is a normal, harmless, and healthy practice that helps the child to derive pleasure from the child's own body. Many parents may have received negative messages as children about their sexual development, and this has led them to view typical sexual behaviors as problematic. Myths must be dispelled concerning the belief that masturbation is a definitive sign of sexual abuse, that it may cause intellectual disability, physical deformity, blindness, poor physical and mental health, facial pimples, hair on the palms of the hand, homosexuality, and sexual perversions. Parents should be aware that masturbation occurs almost universally in children and should be encouraged to avoid punishing or shaming their child for a normal behavior. Negative parental reactions will not reduce the frequency of masturbation, but can lead to feelings of guilt and shame in children. If parents observe masturbatory activity in their child, they may want to suggest to the child the inappropriateness of manipulating their genitalia in public places or in front of others and inform the child that certain practices, such as using the toilet and masturbating, are best carried out in private.

Because local genital irritation, *Candida* infection, or pinworms in rare cases may cause a child to repeatedly touch their genitals, a physical examination helps to exclude such possibilities. Compulsive, overt masturbation among children and adolescents may lead to social ridicule and condemnation, or it may signify a deeper emotional problem. Consultation with a specialist in behavioral disorders of children and adolescents is indicated if the physician suspects that the masturbatory activity is excessive, compulsive, or not easily redirectable or may indicate the presence of a more complicated, troublesome emotional problem. Any masturbatory actions that involve self-harm or are coercive of other children are concerning and warrant additional evaluation and consultation.

The pediatrician should be aware that even with the current societal trends toward sexual openness and enlightenment, myths and feelings concerning masturbation often are deep seated and persistent. Thus, counseling and advice given by the pediatrician may be met with covert or overt resistance by parents or school authorities. The pediatrician should be well

prepared to educate persons responsible for the growth and development of children.

## HAIR PULLING AND TWISTING

Recurrent hair pulling and twisting (*trichotillomania*) is a form of self-stimulating behavior that often indicates the presence of psychological stress. The scalp is the most common area affected; eyebrows and eyelashes are the next most likely sites. The obvious cosmetic damage often results in ridicule by peers and shame for the child. The formation of a hairball, or *trichobezoar*, in the stomach if the child ingests the hair is a serious problem that often results in hospitalization for surgical removal of the accumulated matted hair. This behavior has been reported across all age groups and has a bimodal onset with peaks in the preschool years and in early adolescence (ages 11–13 years). Onset in very early childhood shows no gender bias; however, this behavior becomes more common in females with increasing age. The *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, groups trichotillomania with the obsessive-compulsive and related disorders because it is a recurrent, body-focused, repetitive behavior. Two types of trichotillomania have been described in clinical practice, both of which can coexist in the same individual. In the *focused* type, which is associated with tension before and relief after the hair is pulled, time is set aside to pull the hair. In the second, *automatic* type, the patient is generally unaware of the behavior during the hair pulling or twisting itself and often recognizes the action as senseless and undesirable.

Treatment is usually indicated and behavioral and cognitive behavioral therapy should be used as first-line treatment. Local irritation from a dermatologic condition is rarely the cause of this disorder, but the possibility should be investigated. Referral to a mental health professional is often warranted to investigate possible underlying causes of tension, anxiety, depression, or obsessive-compulsive disorder. Psychotherapy may be required in many of these cases. Research does not support the use of selective serotonin reuptake inhibitors (SSRIs) to treat trichotillomania, but SSRIs can treat comorbid anxiety in children and adolescents. Although studies of the treatment of adult trichotillomania showed significant benefit using N-acetylcysteine (NAC), research had not supported the benefit of NAC for the treatment of children.

## SPECIAL PROBLEMS IN CHILDREN WITH SEVERE MENTAL HEALTH DISORDERS

A broad spectrum of self-stimulating behaviors may be seen in children with developmental disabilities and severe mental health disorders. The behaviors, including body twirling or spinning and hand or arm flapping, are often seen in cases of infantile autism or childhood schizophrenia. Excessive rocking behavior is common in severely intellectually disabled and emotionally disturbed children. In addition, severe self-mutilating behaviors, such as compulsive self-biting,

severe head banging, and skin gouging, may be seen in these disorders and are characteristic of certain metabolic or genetic disorders, such as Lesch-Nyhan syndrome and Cornelia de Lange syndrome. Patients who have Prader-Willi syndrome often demonstrate severe skin picking.

These behaviors are part of a symptom complex in a severe disorder, in contrast to the generally isolated behaviors in typically developing children. The cause is generally linked to the basic disorder and may also reflect the lack, or disordered integration, of sensory stimuli. As previously mentioned, these behaviors can be reinforced by parental/adult reactions and often serve a communication function, eg, the child increases the self-stimulating behavior to receive attention and avoid unpleasant tasks.

All of these cases require treatment for the basic disorder and generally demand special behavioral treatment beyond the scope and expertise of the primary care physician. When the behavior is severe, institutionalization is often required, and methods of treatment include the application of aversive behavior modification techniques; the use of arm and neck restraints, head helmets, and psychotropic medications; and the institution of psychotherapeutic behavioral programs.

### WHEN TO REFER

- Persistence of head banging or rocking beyond the age of 3 years
- Preoccupation with self-stimulating behavior to the point that it interferes with healthy social and emotional interaction
- Presence of accompanying symptoms such as decreased socialization or other behavioral problems
- Causing tissue damage

## Chapter 193 SHORT STATURE

Paul Kaplowitz, MD, PhD

The accepted medical definition of when a child is too short is often at variance with the point at which parents worry about their child's growth. Parents may be concerned when a child is among the shortest in the class or when a younger sibling starts to catch up to the child in question, even if the child's height clearly falls within the normal range. Statistically speaking, the normal range encompasses 2 standard deviations above and below the mean, or approximately between the 97th and the 3rd percentiles. The third percentile may be difficult for primary care physicians (PCPs) to appreciate, given that the lowest curve on many growth charts is the fifth percentile. Furthermore, a single point on a growth chart often will not define whether a somewhat short child has a worrisome growth pattern; therefore, previous growth data should be plotted whenever available, and any suggestion of growth deceleration should be carefully reviewed. An additional complication is that in boys between the ages of 12 and 14 years, growth charts show an upward inflection in height as boys start their growth spurts; thus, a somewhat short boy who is prepubertal will seem to fall further behind, even though he is continuing to grow at a normal rate. The growth charts published by Tanner and Davis in 1985 make this point clear because they have a separate line for short, late-maturing boys and girls.

### DIFFERENTIAL DIAGNOSIS

Constitutional growth delay (CGD) and familial short stature (FSS) are the 2 most common causes of short stature. In the Utah Growth Study, which, through school screening, identified 555 children who were below the third percentile and growing at less than 5 cm per year; 81% of these children had CGD, FSS, or a combination of the 2 conditions. In CGD, children are healthy and growing below but parallel to the third percentile line. Birth weight is normal, but between 6 and 24 months linear growth and weight track downward to the third percentile or below; after age 3, children follow their own curve parallel to the low end of the growth chart. Children with CGD typically have a delayed onset of puberty and growth spurt and usually end up with heights in the lower half of the normal range. A characteristic finding is that the child has a bone age that is delayed by 2 or more years.

Familial short stature is quite easy to recognize when the child is healthy, growing at a normal rate below the third percentile, and 1 or both of the parents are quite short. Unlike CGD, children with FSS tend to have puberty at a normal age and achieve an adult height within 2 to 3 inches of their adult target height, which can be calculated by averaging the heights of the parents and adding 2.5 inches if the child is a boy and subtracting 2.5 inches if a girl. Some children may have features of both CGD and FSS.

### Short Stature Associated With Syndromes and With Being Born Small for Gestational Age

Short stature associated with a syndrome should be considered when a very short child has a dysmorphic appearance, particularly if born small for gestational age (SGA) (eg, birth weight of  $\geq 2,500$  g at term).

Turner syndrome should be a consideration in any girl whose height is well below the third percentile, but certain features make the diagnosis more likely. Lymphedema in the newborn period or frequent ear infections well past 2 years of age are common. The most common physical findings include a narrow, high-arched palate, cubitus valgus (a large angle at the elbow when the arms are stretched out), and upturned fingernails. The classic webbed neck is seen in only 40%. Approximately 15% have congenital heart disease, usually coarctation of the aorta. Mean birth weight is 2,785 g; thus, many patients are not born SGA.

Many less common syndromes exist in which dysmorphic features are associated with short stature. In Russell-Silver syndrome, the most characteristic features are a history of being born SGA and having a triangular face with a down-turned mouth. Noonan syndrome may be suggested by the finding of pulmonary stenosis and facial features that include a flat nasal bridge, hypertelorism, and ptosis.

Short stature associated with SGA is diagnosed when a child born SGA fails to catch up to the normal range in height by 2 years of age. Many of these children have no dysmorphic features, and no defined cause can be found for their intrauterine growth restriction.

### Chronic Illness and Nutritional Disorders

A chronic illness or nutritional disorder should be considered in short children whose weight is further below the curve than their height (or whose body mass index is below the 10th percentile for age).

Inadequate calories, rarely a result of poverty in the United States because high-calorie foods are inexpensive, is sometimes seen in the setting of a child who is on a self-imposed or parent-imposed restrictive diet to avoid gaining weight or to lower cholesterol levels. The extreme example of this situation is anorexia nervosa.

Inflammatory bowel disease, though rarely the cause of undiagnosed short stature, may be suspected in a child whose growth has been normal but then shows a marked falloff in both height and weight, particularly in the presence of gastrointestinal (GI) symptoms such as abdominal pain, early satiety, and blood in the stool. Growth attenuation may start when GI symptoms are relatively mild or even before they become apparent.

Celiac disease, or gluten enteropathy, is a common cause of short stature in Europe (up to 8% in some studies), although its frequency in the United States seems to be much lower. Abdominal pain, distension, and loose stools may suggest the diagnosis, but most short children with celiac disease have few if any GI symptoms.

Renal disease can cause short stature, but only rarely is it diagnosed solely because of an abnormal

growth curve. Renal tubular acidosis and chronic renal failure are the 2 renal conditions that can cause growth failure and that can be ruled out by appropriate screening tests.

### Poor Growth Associated With Medications

Children treated with stimulant medications for attention-deficit disorder may have growth attenuation starting either at the time the medications are begun or between 9 and 12 years of age. One recent study, which included younger patients with a mean age of 4.4 years, found a 20% reduction in height velocity and a 50% reduction in weight gain in treated children. Although the common belief asserts that decreased appetite is responsible for the slow growth, many of these children are not underweight, and the explanation for their slow linear growth is still unknown.

Chronic glucocorticoid therapy is another cause of short stature, mostly seen in children with such conditions as rheumatoid arthritis and inflammatory bowel disease treated with daily oral prednisone. The effect on the growth of children treated long-term with inhaled corticosteroids for asthma is clearly much less than for systemic glucocorticoids, although monitoring of linear growth may occasionally detect evidence of growth suppression.

### Endocrine Disorders

The Utah Growth Study reported that less than 5% of short, slowly growing children had a defined endocrine disorder. A major clue that an endocrine cause may exist is that height is often more affected than weight.

Growth hormone (GH) deficiency is not a common cause of short stature. In the Utah Growth Study the incidence in school aged children was estimated at 1:3,480. A 2004 study from Belgium, which considered all children diagnosed with GH deficiency between 1985 and 2001, estimated the incidence at 1:5,600. The diagnosis should be suspected in children who are well below the third percentile in height and falling further below over time. One suggestive physical finding is an increase in subcutaneous fat that is greater in the trunk area than elsewhere. Most cases are congenital; birth weight is usually normal but a falloff in growth occurs starting late in the first or in the second year of life. In the much less common acquired cases, a period of normal growth is followed by deceleration; central nervous system symptoms such as severe recurrent headaches may be part of the clinical picture. Once a diagnosis of acquired GH deficiency is established, the endocrinologist will order brain imaging to look for a tumor in the area of the pituitary gland. Milder or partial forms of GH deficiency are difficult to distinguish from CGD and FSS based on growth pattern, physical findings, and laboratory tests. The apparently higher frequency of GH deficiency in recent years is, in large part, because GH testing done in the United States has many false-positive results, and many normally growing children fail the test using the accepted cutoff of 10 ng/mL.

Acquired hypothyroidism, when severe, can cause slowing of growth or even complete growth arrest.

Other symptoms, including fatigue and cold intolerance, are often present, and most children will have a goiter. Acquired hypothyroidism needs to be excluded as a possibility in any child with documented growth deceleration, even if height is still above the third percentile.

Although iatrogenic Cushing syndrome is not uncommon, true endogenous Cushing syndrome is extremely rare. Rapid weight gain in the trunk, rather than generalized in distribution, accompanied by a slowing of linear growth are the key findings. Moon facies and purple abdominal striae are often seen, as well as increased skin pigmentation.

### Idiopathic Short Stature

*Idiopathic short stature* (ISS) is a term used to describe moderately to severely short children who do not meet the criteria for CGD and FSS (eg, they often have a subnormal rate of growth); and in whom no cause for their poor growth is found after extensive testing. Studies have shown that most children with ISS respond to a variable degree to GH and see a modest average improvement in adult height. The US Food and Drug Administration (FDA) in 2003 approved GH for children at or below the first percentile with an anticipated adult height (based on bone age) below the normal range. However, some insurance companies refuse to cover GH to treat ISS, arguing that no medical condition causing the growth problem exists and that treatment is cosmetic.

## EVALUATION

### History

The most helpful information in evaluating the short child is the growth curve. If the growth rate has been normal for the previous 2 or more years, then the child most likely has CGD or FSS and is unlikely to have a defined, treatable cause. A single height point that falls off the established curve is often a measurement error and should be rechecked. A history of stimulant medications or glucocorticoid use might be a key piece of information. Many children with chronic growth-limiting illnesses have a decreased energy level and may have a poor appetite, although many short, healthy children are also described as picky eaters. An abnormal stool history should make the PCP think of malabsorption, celiac disease, or inflammatory bowel disease.

Heights of parents and grandparents and growth percentiles of siblings should be reviewed because they may suggest FSS in a healthy child who is short but growing at a normal rate. Approximately two-thirds of children with CGD have a family history of a parent who was a late maturer (eg, mother's menarche after age 14 or a father who continued to grow after high school).

### Physical Examination

Most short children do not have any physical findings that point to a specific diagnosis. A child with decreased subcutaneous fat stores and weight more affected than height may simply not be getting enough calories or may have bowel disease or another chronic

illness. Conversely, a short child who is relatively pudgy (particularly if excess rippled fat is present over the trunk) may have GH deficiency. Dysmorphic features may provide a clue to a syndrome associated with short stature. In girls, the PCP should look for, among other things, a high-arched palate, cubitus valgus, and fingernails that bend upward, which may point to a diagnosis of Turner syndrome. An enlarged thyroid may be the only clue that a short child has hypothyroidism. Pubertal staging should be done on any short child who is 10 years or older. A short, healthy 14-year-old boy (or, less often, a short, healthy 13-year-old girl) who is still prepubertal is most likely to have a diagnosis of CGD. A child who has a flattened growth curve at 13 to 16 years of age and who, by examination, is found to be in the late stages of puberty has completed or has nearly completed growing, and nothing can be done to increase the individual's adult height.

### Laboratory Evaluation

Primary care physicians should resist the temptation to order multiple laboratory tests for a child who is only mildly short (at or above the third percentile) and whose growth rate seems to be normal. In this situation, a clinically significant abnormal test result that will explain why the child is short is rarely found. Most growth specialists prefer either to order a very few tests on such children or to perform no tests at all, particularly if everything points to a diagnosis of CGD or FSS.

Ordering screening tests in advance of a visit with a specialist might be appropriate if the child's height is well below the third percentile or if growth deceleration that cannot be explained by medication is well-documented. However, the specialist can order any needed test at the first consultation.

Insulin-like growth factor 1 (IGF-1) is still the best screening test if GH deficiency is suspected, although many children with CGD have IGF-1 levels that are borderline low for age. IGF-binding protein 3 has not lived up to its initial promise as a better screening test for GH deficiency than IGF-1, and it is not worth ordering routinely. A random GH level is of no value because of the pulsatile nature of GH secretion.

Thyroid testing should be limited to free thyroxine (T4) and thyroid-stimulating hormone (TSH) assessment, which will identify both primary and secondary hypothyroidism. Triiodothyronine (T3), T3 uptake, and thyroid antibodies are not helpful as screening tests for short children. A borderline increased TSH (in the 5.5- to 10-mcU/mL range) with a normal free T4 is usually a normal variation and will not explain poor growth.

Complete blood count and erythrocyte sedimentation rate are mainly useful in the occasional child in whom inflammatory bowel disease is suspected. A microcytic anemia may be a clue to occult GI blood loss. Either tissue transglutaminase immunoglobulin A (IgA) antibody or antiendomysial antibody are good tests to screen for celiac disease. Antigliadin IgG and IgA are much less specific and are not worth the extra cost.

A comprehensive metabolic profile will rule out electrolyte disturbances, kidney disease, and liver disease, all of which are rare causes of short stature.

### Imaging Studies

The only radiographic examination that should be considered is the bone age film, which is not a very useful diagnostic test because most children who are short for any reason (aside from genetic short stature) will have a bone age delay of a year or more. The clinician may order a bone age film in a child over 7 to make a height prediction when either CGD or FSS is suspected.

## MANAGEMENT

Healthy children who are at or above the third percentile and growing at a normal rate need not be referred to a specialist because the chances of finding a treatable cause for their short stature are small. If the parents insist on seeing a specialist, then they should be told that the child will not likely need or be eligible for coverage of GH therapy. Such children should have their growth carefully measured and plotted at each visit to make sure they are not dropping below the third percentile in height. A few children report having poor self-esteem because they are shorter than most of their peers, and they may be subjected to teasing or bullying; referral to a psychologist may be more helpful than to an endocrinologist.

Infants or children who are maintaining linear growth at or above the third percentile but whose weight is consistently below or has recently fallen below the third percentile almost never have an endocrine problem. If weight gain is slow but fairly consistent in a thin child, this may be a normal variation; parents may say that they were thin at the same age. If weight gain is persistently poor or there is weight loss, then referral to a GI or nutrition specialist should be considered.

The child who is still in the normal range but who is crossing percentiles may present a dilemma. Between 6 and 24 months, such percentile shifts in height and weight are common, especially in patients with CGD, and a stable growth curve is usually established between 2 and 3 years of age; therefore referral may be deferred if the child is healthy. If the child crosses 1 percentile channel (eg, from the 25th to the 10th percentile) over 3 or more years, and if the history and examination reveal nothing abnormal, then a cause will not likely be found. Children who cross more than 1 percentile channel in a period of less than 3 years have a greater chance of having a definable cause for their short stature. The most common cause of this growth pattern is the use of stimulant medication in children with attention-deficit disorder.

Parents of children who are short enough to be referred can be told that screening tests and a period of observation are needed before any decision can be made regarding the possible need for GH therapy. Such children are best referred between the ages of 3 and 6; children who are pubertal or on the verge of puberty are usually too old to derive much benefit from GH therapy.

## WHEN TO REFER

- Any child whose height is below the third percentile, particularly if the height is falling further below the normal range over time. Children who are below the first percentile have an even better chance of qualifying for GH therapy because they are more likely to have true GH deficiency; and if they do not have GH deficiency, then they may still meet the FDA criteria for GH treatment for ISS.
- A child with a history of intrauterine growth retardation who was born SGA and who has not caught up to the normal range by age 2 years or older. The FDA has approved the use of GH in such children without the need for GH testing. A dysmorphic child with a history of intrauterine growth retardation should also be referred to a geneticist to try to make a specific diagnosis.
- A child who is within the normal range in height but has experienced a drop-off in linear growth of more than 1 percentile channel over a period of less than 3 years, or who has shown documented growth arrest for a year.
- A child with short stature who has not started puberty by age 14. This situation occurs mostly in boys with CGD; and in many cases, when the boy is anxious to start his growth spurt sooner rather than later, treating such boys with a brief course of testosterone injections is appropriate.

## Chapter 194

**SLEEP DISTURBANCES  
(NONSPECIFIC)**

Mark L. Splaingard, MD; Anne May, MD

Sleep is necessary for human development and well-being, yet it has unique vulnerabilities in childhood that can manifest, for example, as central congenital hypoventilation syndrome or the inability of most primary school-aged children to awaken to very loud noises such as fire alarms during slow-wave sleep. Estimates of prevalence in children vary most widely for behavioral sleep problems like insomnia, as opposed to organic sleep problems like obstructive sleep apnea (OSA), with interesting cultural and ethnic variations. Underreporting by parents and underdiagnosis by primary care physicians have been issues, with sleep problems conservatively estimated to occur in approximately 25% of healthy children younger than 5 years and in up to 80% of children with special needs. Because many sleep difficulties can be managed successfully in the primary care setting, pediatricians are ideally positioned to anticipate, recognize, and treat most sleep problems and to refer children to a specialist when appropriate. Successful management of pediatric sleep problems often results in improved sleep and daytime function for all members of the household.

A strong subjective component can be found for many pediatric sleep problems, as in the typical case of the toddler with night awakenings who wants to get in the parental bed:

- The parents in family A do not consider this desire as a problem. Both parents are good sleepers and do not care if their child sleeps in their bed.
- The parents in family B believe strongly that the child does not belong in their bed and that their bedroom is the only place they have to themselves.
- The mother in family C lives with her own mother and is raising two children. They live in a small apartment in which the two children share a bed.
- The parents in family D own a bed-and-breakfast business and live on the premises. They do not want their child in their bed but cannot afford to have a crying child wake the guests.
- The parents in family E have let their child into their bed in the past, but another infant is due in 3 months, and they would like their child to transition to spending the night in her own bed.

These examples illustrate the variety of responses to a common sleep issue in the young child. All of these families have caring parents and normally developing toddlers. Some of the parents regard the behavior as a sleep problem, whereas others do not. The parents in family B are more likely to consult a pediatrician about the child's sleep than the parents in family A.

Some sleep problems such as OSA are more likely to be acknowledged as problems by most families, although perceptions may vary. A hearing-impaired parent may not complain of a child's snoring. A parent who is a light sleeper is more likely to take note of a

child's sleep disruptions than a parent who is a sound sleeper. Parents frequently consult pediatricians about sleep issues, and the pediatrician should recognize the range of sleep problems and the variability in parental perception of these problems.

**DEVELOPMENT OF SLEEP**

The development of physiologic sleep patterns is predictable (Table 194-1). It begins in utero; by 28 weeks gestational age, rapid eye movement (REM), or active sleep, can be discerned via fetal ultrasound. Non-rapid eye movement (NREM), or quiet sleep, appears at 32 weeks gestational age. At term, newborns have discrete sleep cycles, lasting 50 to 60 minutes, with awakenings every 2 to 6 hours. These sleep cycles are composed of alternating periods of equal amounts of quiet and active sleep. Quiet sleep is characterized by body stillness, regular respirations, and normal muscle tone. During active sleep, the infant has decreased muscle tone with frequent body movements, including eye movements and irregular respirations. The total daily amount of reported sleep at 1 month of age ranges widely from 9 to 19 hours, with an average of 14 hours (Table 194-2).

By 4 months of age, mature sleep stages begin to emerge, and day-night sleep patterns are well consolidated. Infants have their longest sleep periods at night and 3- to 4-hour periods of wakefulness during the day. By 6 months, circadian rhythms begin to display activity similar to rhythms in adults and are well established by 1 year of age. By 3 years of age, the child reaches an adult pattern of sleep, with each discrete cycle of NREM and REM sleep lasting 70 to 100 minutes.

At the beginning of the night, a child progresses rapidly through stage N1 and stage N2 sleep and enters slow-wave sleep (stage N3) for much of the first third of the night. During slow-wave sleep, the child is difficult to awaken. (Many parents will recognize this period as the time of night that they can vacuum or listen to loud music without waking the child.) Subsequent sleep cycles have decreased amounts of slow-wave sleep and increased amounts of stage N2 sleep and REM sleep. Dreaming takes place mainly during REM sleep. REM episodes become longer and more intense later in the sleep period; thus, children are more likely to complain of bad dreams during the last portion of the night. In addition, sleep-disordered breathing (SDB) is likely to be most prominent during REM sleep. This tendency is important to recognize, given that this time of night is when parents are least likely to be awake and watching the sleep patterns of their children.

The amount of sleep that children need varies by age, but most children in the early school years need at least 10 hours of sleep (see Table 194-1). Children who are sleep deprived are sometimes sleepy but are more often irritable, inattentive, or hyperactive. Adolescents need sleep as much as younger children do, but they are less likely to get as much sleep as they need.

Humans have internal clocks that operate on a cycle of approximately 24 hours. These 24-hour cycles, known as *circadian rhythms*, are controlled by the

**Table 194-1** Sleep Developmental Milestones

GESTATIONAL AGE (WK)	SLEEP PATTERNS
10	Spontaneous fetal movements are identified.
24	Neither quiet nor active sleep can be identified between 24 and 26 weeks. Early premature (24–27 weeks) neonates have atypical sleep state characteristic of active and quiet sleep.
28	Active sleep is identified by 28 to 30 weeks by eye, body, and irregular respiratory movements. Chin tone does not become tonic before 36 weeks. Rhythmic cycling period of activity and quiescence is identified between 28 and 32 weeks.
30	Typical sleep states begin to emerge at 30 weeks.
32	Tracé alternant pattern associated with quiet sleep appears at 32 to 34 weeks. Occipital predominance of delta activity is striking at 31 to 32 weeks. At 32 weeks, EEG differences among wakefulness, active sleep, and quiet sleep develop.
34	Active sleep is 60% of TST.
37	Sleep organization at 37 weeks similar to term newborn.
40	Sleep onset through active/REM (REM within 15 minutes of sleep onset). Three distinct sleep states in term newborn: (1) REM (active), (2) NREM (quiet), and (3) indeterminate. Newborn sleeps 16 to 17 of 24 hours. Active sleep 50% of TST in term infant. Newborn sleep cycle is 50 to 60 minutes (range, 30–70 minutes), 58% active, and 39% quiet. Periodic breathing is noted, particularly in active sleep.
46	Tracé alternant present in quiet sleep in normal infants is not seen after 46 weeks.
48	Sleep spindles appear. Premature infants show spindle development approximately 4 weeks in advance of full term. Periodic breathing becomes rare after 48 weeks.
3 months	NREM sleep stages begin to appear. By 3 months, sleep-onset REM is no longer present. By 3 months, 60% of sleep is quiet sleep, and 40% is active sleep. Lack of sleep spindles after 3 months is associated with hypothyroidism.
4 months	Sleep shifts to nighttime <i>settling</i> by 12 to 16 weeks. Slow-wave sleep recognized at 3 to 4 months. Adult sleep stages at 4 to 5 months. Infant asleep 14 to 15 hours a day by 4 months. By 16 weeks, sustained wake periods are as long as 3 to 4 hours.
6 months	By 6 months, 90% of infants have more NREM sleep than REM sleep.
8 months	REM sleep occupies 30% of TST. Total sleep duration is 13 to 14 hours a day by 6 to 8 months of age.

EEG, electroencephalogram; NREM, non-rapid eye movement; REM, rapid eye movement; TST, total sleep time.

**Table 194-2** Average Sleep by Age

AGE	TOTAL SLEEP DURATION (hr)	2%–98%	MEAN DAYTIME SLEEP DURATION (hr)	DAYTIME NAPPING CHILDREN (%)
1 mo	14	9–19	5.5	100
3 mo	14	10–18.5	5.0	100
6 mo	14.2	10.4–18.1	3.4	100
9 mo	13.9	10.5–17.4	2.8	100
12 mo	13.9	11.4–16.5	2.4	100
18 mo	13.6	11.1–16	2.0	96
2 yr	13.2	10.8–15.6	1.8	87
3 yr	12.5	10.3–14.8	1.7	50
4 yr	11.8	9.7–14.0	1.5	35
5 yr	11.4	9.5–13.3	0	8
6 yr	11.0	9.3–12.6	0	5
7 yr	10.6	9.2–12.1	0	1
8 yr	10.4	9.0–11.7	0	0
9 yr	10.1	8.8–11.4	0	0
10 yr	9.9	8.6–11.1	0	0
11 yr	9.6	8.3–10.9	0	0
12 yr	9.3	8.0–10.7	0	0
13 yr	9.0	7.7–10.4	0	0
14 yr	8.7	7.3–10.1	0	0
15 yr	8.4	7.0–9.9	0	0
16 yr	8.1	6.6–9.6	0	0

hypothalamic suprachiasmatic nucleus. Most people have cycles that are not exactly 24 hours in length, and external time cues help reinforce the 24-hour schedule. The time cues are known as *zeitgebers* (German for *time givers*). The most powerful cue is exposure to bright light; other cues include social interaction, food, and exercise. Circadian rhythms are usually synchronized or *entrained* with light–dark cycles. Infants develop these circadian rhythms over the first few months of life, with rhythmic secretion of melatonin by 12 weeks in term infants. Circadian rhythm sleep disorders occur when a person’s sleep is of normal duration but occurs at a time that does not allow adequate sleep in the context of the person’s life. For example, an adolescent who is unable to fall asleep until 4:00 am and cannot wake before noon is said to have a circadian rhythm disorder (sleep-phase delay) and is likely to have problems functioning in a usual school environment. If, however, a person with the same sleep-phase delay works at night, then the sleep-phase delay is not considered a disorder.

SLEEP EVALUATION

Children rarely complain of sleeping problems. A parent or other caregiver usually initiates the diagnostic evaluation. The most common complaints are the child’s inability to fall asleep or remain asleep, daytime sleepiness, and abnormal behaviors during sleep (snoring, gasping, or yelling). In sorting out a concern about sleep, history is the major initial diagnostic tool.

Questionnaires for general screening or for evaluating sleep complaints may be helpful in gathering data in busy practices. One simple, 5-item pediatric sleep screening instrument is BEARS (Bedtime problems, Excessive daytime sleepiness, Awakenings at night, Regularity and duration of sleep, and Snoring). The key areas explored on the BEARS parent questionnaire can lead to further open-ended questions by the practitioner to determine the level of parental concern (or to elicit maladaptive patterns if no concern is expressed) and to help formulate a differential diagnosis (Table 194-3). Having the parents keep a sleep chart is helpful (Figure 194-1); it may demonstrate a consistent

Table 194-3      Questions to Clarify Sleep Problems

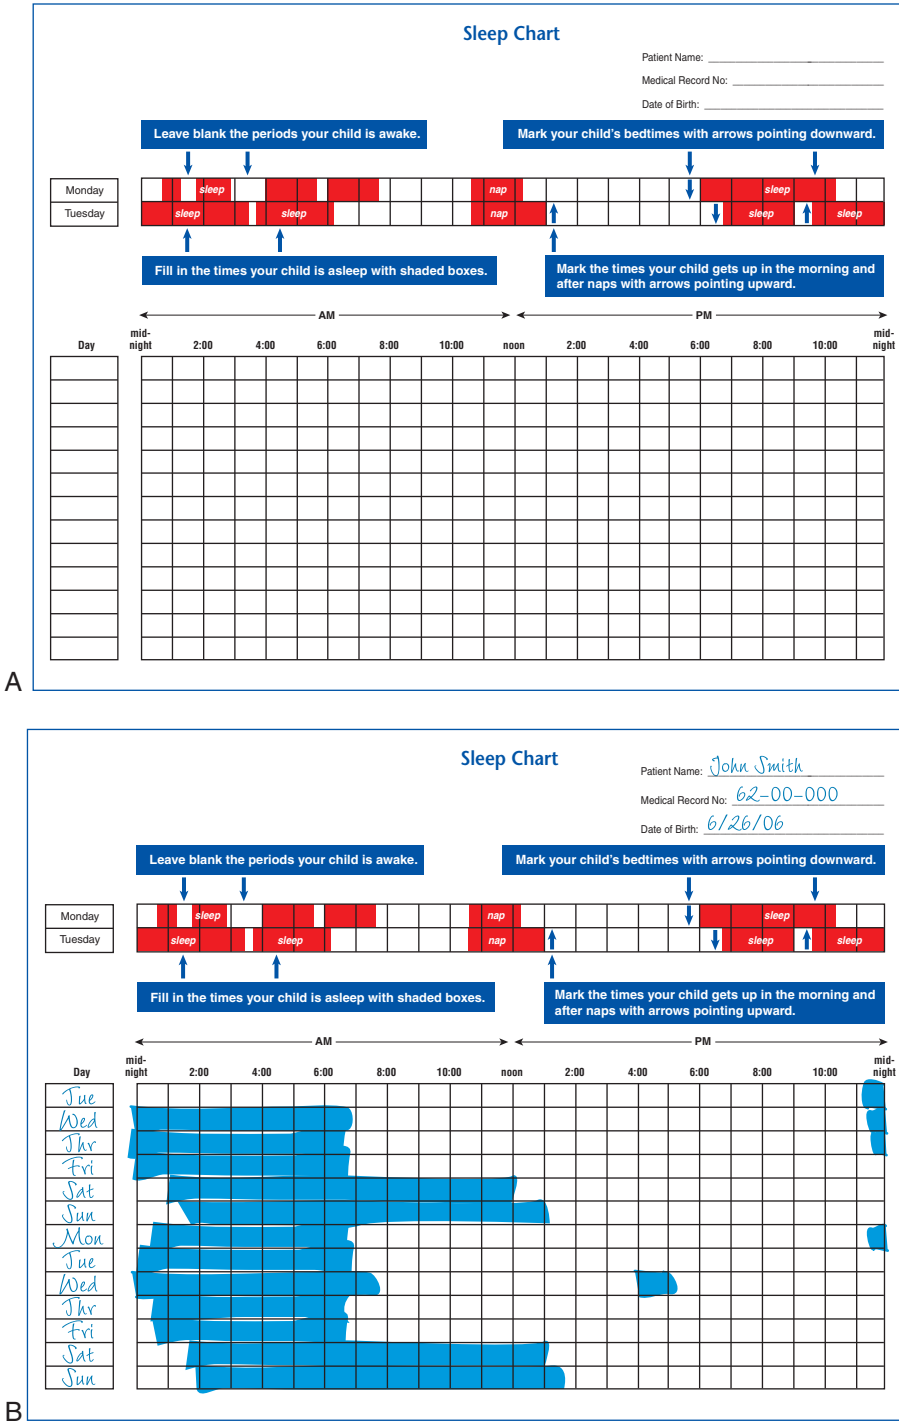

QUESTIONS	TO CLARIFY
<b>TO THE PARENTS</b>	
Do you have any concerns about the child’s sleeping?	Problem versus disorder
How do you think the child is sleeping compared with other children of similar age?	Traumas or stress
When and how did the child’s sleep problems start?	Secondary gain
Did other changes in the child’s life occur around this time?	Traumas or stress
• What methods have you tried to solve this problem?	
• What ideas have you had about solving this problem?	
• What have others told you about this problem?	
What is the atmosphere in the room where the child sleeps with regard to temperature, darkness, noise, presence of siblings, and type of bed?	Environmental sleep disorder
When is the last time the child eats before falling asleep?	Inadequate sleep hygiene
	Sleep-onset association disorder
Does the child consume any caffeine or nicotine in the evening?	Insomnia caused by substance or drug effects
What is the child doing just before bedtime?	Inadequate sleep hygiene
	Limit-setting disorder
	Bedtime resistance
What routines do you use to put the child to bed?	Inadequate sleep hygiene
	Limit-setting disorder
	Bedtime resistance
What exactly do you do at bedtime?	Sleep-association disorder
How does the child act at bedtime?	Bedtime resistance
Where and with whom does the child sleep?	Sleep-association disorder
What does your spouse or partner think about this arrangement?	Family conflict
Who else has something to say about the child’s sleeping?	Family conflict
Is the child already asleep when you put him or her in the crib or bed?	Sleep-association disorder
What time is the child put in bed?	Limit-setting disorder
	Inadequate sleep hygiene
	Circadian disorders
What time is the child asleep?	Limit-setting disorder
	Inadequate sleep hygiene
	Circadian disorders
Does the child do anything unusual during sleep?	Sleep-disordered breathing
Snoring, gasping, apnea?	

Continued

**Table 194-3** Questions to Clarify Sleep Problems—cont'd

QUESTIONS	TO CLARIFY
<b>TO THE PARENTS</b>	
Leg kicking, thrashing?	Periodic limb movements, restless leg syndrome
Bed wetting?	Nocturnal enuresis
Shaking, screaming?	Nocturnal seizures
	Parasomnias
What times does the child wake up?	Night feeders
	Sleep-association disorder
How does the child appear, or what does he or she do after waking?	Parasomnias
	Developmental night waking
	Trained night feeders
	Seizures
What works to resettle the child?	Sleep-association disorder
	Trained night waking
	Trained night feeding
	Gastroesophageal reflux
How is that process for you?	Secondary gain
Does the child snore or seem to stop breathing during the night?	Sleep-related breathing disorder
What time is the child up for the day?	Circadian disorders
	Mood disorders
Is the schedule the same on weekends, or does the child sleep in?	Limit-setting disorder or sleep-phase delay
How does the child wake up in the morning?	Circadian disorder or sleep-phase delay
When you wake the child, does he or she seem rested and cheerful?	Circadian disorder or sleep-phase delay
	Inadequate sleep
What time does the child eat in the morning?	Circadian disorder or sleep-phase advance
	Limit-setting disorder
If older than 3 years, does the child remember what happened during the night?	Parasomnia (not remembered)
	Nightmares (remembered)
	Panic attacks (remembered)
Does the child fall asleep during the day? If so, then when, where, and for how long?	Circadian disorders
How is the child settled for naps?	Idiopathic hypersomnia or narcolepsy
	Sleep-association disorder
Does the child sleep differently at other people's houses? If so, then how?	Limit-setting disorder
	Sleep-association disorder
Has the child ever been given any medications for sleep?	Limit-setting disorder
	Insomnia caused by a psychiatric or behavioral condition
What was the medication? How did it work?	
Has anyone in the family ever had sleep problems? Did either of you have sleep problems as kids?	Genetic factors (short or long sleeper)
<b>TO THE CHILD</b>	
What do you think about before you go to sleep?	Anxiety or mood disorder
	Limit-setting disorder
How do you feel when you wake up in the night?	Nightmares
	Disorders of arousal
	Anxiety or mood disorders
Do you still feel sleepy in the morning?	Inadequate sleep
	Circadian disorder or sleep-phase delay
How do you feel about this sleeping problem?	Anxiety
	Secondary gain
What do you think your parents should do about this?	Secondary gain
How are your concentration and grades at school?	Sleep-related breathing disorder
	Sleep-phase delay
	Periodic limb movements disorder
	Narcolepsy
	Idiopathic hypersomnia

**Figure 194-1** A, Sleep log. B, Sleep log showing sleep-phase delay.

pattern, which may improve with the use of sleep hygiene principles (Box 194-1). A general medical, developmental, and mental health history assessment should include any medications, herbal products, drugs, alcohol, or tobacco use. Given that many sleep disorders have a strong familial component, a history of parental sleep issues may be helpful.

Parental perceptions and differences of opinion about sleep often are critical in problem-solving efforts. Co-sleeping (one or both parents sharing a bed with one or more children) serves as a good example of this point. Co-sleeping is a common practice in many cultures and households. When it is agreeable to both parents, co-sleeping is not associated with

**BOX 194-1 Sleep Hygiene Principles**

General principles of sleep hygiene apply at any age, but specifics may vary with the child's age.

1. Establish a good sleep environment that is dark, quiet, and comfortable and has a steady, slightly cool temperature. Sleep should be in the same place for night and naps as much as possible. The bed or crib should be used as a place for sleep and not as play area or playpen while awake.
2. Establish a soothing bedtime routine that involves friendly interaction between the parent and the child. This routine may include a snack and then tooth brushing, use of the toilet, and then story, prayer, or talking time with children in their own bed. The parent should leave the room while the child is still awake.
3. Infants should be fed in a parent's arms and placed in the crib without a breast or a bottle in their mouth. Avoid excessive feeding close to bedtime to reduce the need to void during the night.
4. The child should be put to bed when moderately tired to reduce bedtime resistance.
5. For children whom the parents would like to have sleep in their own crib, teach them the skill of falling asleep on their own by avoiding pacifiers or body contact with the parent as they drift to sleep (self-soothing). This method enables children to go back to sleep on their own after waking during the night.
6. Avoid changing the routine because of demands or tantrums at bedtime, which can quickly develop into a pattern.
7. No television, computer, or any electronic screens should be in the child's room because research shows that video screens will prolong sleep onset and delay bedtime. It is advisable to enforce an electronic curfew for older children and adolescents to facilitate preparation for sleep without distraction and also prevent further use during the night without parental supervision.
8. Try to keep a consistent schedule for bedtime, naps, and morning wake up, which will help the child maintain regular circadian rhythms. Naps should not be taken too close to bedtime.
9. Remember that television programs and movies may be frightening or stimulating. Arguments between parents or other family members may also be distressing. Try to keep the household atmosphere calm in the evening.
10. Keep track of activities that seem to lead to sleeping problems. If active play or video games lead to problems, then stop them 1 or 2 hours before bedtime. Caffeine and nicotine can disrupt sleep. Avoid caffeine at least 6 hours before bedtime.

greater-than-average behavioral or emotional problems in the child. If, however, co-sleeping is a source of discord between parents or reflects a parent's inability to manage the child's behavioral bedtime problems, then it should be addressed as a sleep problem. When co-sleeping is planned, parents should agree on the desired duration. The pediatrician may help the parents by telling them that this arrangement is easier to change before 6 months of age (if an end is intended during infancy). Bed sharing with infants remains controversial particularly with mothers who smoke and when the infant is younger than 11 weeks.

Parental mental health needs to be screened in assessing sleep difficulties because the emotional stability of parents may affect both the perception of problems in children and the ability to carry out a treatment plan. Histories from babysitters or relatives who observe the child's sleep may be diagnostic, especially when problems seen at home are not seen in these settings. The family may provide audiotapes or videotapes that may be helpful.

The history is often diagnostic, but some patients need an overnight sleep study for further assessment. An overnight sleep study or polysomnogram consists of the following:

- Electroencephalogram (EEG) to identify sleep stages

- Electromyelogram of chin activity to help identify decreased tone during REM sleep
- Leg electromyogram to measure leg movements
- Electrooculogram to identify eye movements seen in REM sleep
- Electrocardiogram to monitor cardiac rate and rhythm
- Nasal and oral thermistors to measure airflow
- Thoracic and abdominal belts to measure chest and abdominal movements during breathing (helpful in demonstrating increased or decreased respiratory effort)
- Pulse oximetry to measure oxygen saturation
- End-tidal carbon dioxide monitoring to indirectly measure hypoventilation

All of these measurements provide clinically useful information about sleep stages, sleep disruption, respiratory status during all sleep stages, leg movements, and changes in cardiac rate and rhythm during sleep. The sleep study also provides a picture of the relationship of sleep-related measurements. For instance, OSA may cause arousals, cardiac deceleration, and oxygen desaturation; these findings may be mild during NREM sleep but profound during REM sleep.

Overnight sleep studies are attended by a sleep technologist who attaches monitoring sensors and adjusts them during the night. The technologist also

provides observations about the child's sleep that may be invaluable in making an accurate diagnosis.

Extended-montage video electromyograms may be incorporated into the polysomnogram to diagnose nocturnal seizures. Haplotyping, karyotyping, or fluorescent in situ hybridization studies can be helpful for diagnosing some of the genetic conditions associated with sleep disorders such as congenital central hypoventilation syndrome, Rett syndrome, Smith-Magenis syndrome, and Prader-Willi syndrome.

## CLASSIFICATION OF SLEEP DISTURBANCES

Sleep disturbances in children can be categorized according to the *International Classification of Sleep Disorders*, second edition.

- Behavioral insomnia of children
- Sleep-related breathing disorders
- Circadian rhythm disorders
- Parasomnias
- Sleep-related movement disorders
- Hypersomnias

## MATURATIONAL OR BEHAVIORAL ISSUES

### Day-Night Reversals

The earliest parental complaint about sleep is often day-night reversal, occurring around 2 weeks of age. This problem is predictable because consolidated nocturnal sleep has not yet developed. Parental concerns provide the pediatrician a valuable opportunity to assess parental coping skills and help parents understand the normal unfolding of the child's physiologic regulation. Day-night reversals can be shifted by establishing a general bedtime, keeping the lights off or low, and keeping handling and interaction to a minimum during nighttime feedings. In the morning, lights should be bright and social interaction encouraged. Lack of sleep at this age is unusual and should alert the clinician to medical problems, especially if associated with irritability.

### Delayed Settling

Another common problem is a delay in the much desired milestone of sleeping through the night. One definition of settling or sleeping through the night is 5 hours of continuous sleep after midnight for 4 consecutive weeks. Unrealistic parental expectations for sleeping through the night are common, and pediatricians need to carefully address misperceptions about how well a child should sleep. Anders observed that 44% of parents of 2-month-olds reported that their child slept throughout the night when, in fact, actual recording on time-lapse videotape showed that only 15% actually slept throughout the night without awakening.

The issue of sleeping through the night may have important ramifications for the breastfeeding infant. Despite the widely recognized and undisputed advantages of human milk for infants, the duration of

lactation in the United States is still well below the recommended goal of 50% at 6 months in all ethnic groups. The perceptions of normal maternal and infant sleep patterns may be an important factor in failure to sustain lactation. Although breastfed infants are typically assumed to feed more frequently and have shorter meal intervals than bottle-fed infants, widely disparate differences in sleep patterns, crying, fussiness, and colic behavior between breastfed and bottle-fed infants have been reported. The perception that breastfed infants typically *settle* at an older age than bottle-fed infants and awaken more frequently at night is quoted in the popular press as an *advantage* of formula feeding. As a corollary, a mother's need for an uninterrupted night's sleep may inadvertently promote the early cessation of breastfeeding.

In fact, breastfeeding need not be associated with increased night waking by 12 weeks of age; both breastfed and bottle-fed infants can respond to behavioral interventions aimed at increasing sleep time during the night. Additional evidence is emerging that continuing lactation can actually increase maternal slow-wave (restorative) sleep because of increased circulating prolactin levels. The circadian rhythm of tryptophan secretion in mother's milk may help promote nocturnal infant sleep and is being mimicked by investigation of varying amounts of tryptophan in day-night formulas.

Infants who appear to have a low threshold of sensitivity by temperamental disposition also tend to settle later. Premature infants tend to settle around the time expected for their gestational age, although variability is greater than among full-term infants. Delays in central nervous system (CNS) maturation often are associated with delays in settling. Infants with frank neurologic impairments may not only be delayed in settling but also have other medical issues that need to be addressed to allow settling to occur.

### Sleep-Onset Associations

Infants and children develop habits of falling asleep in accustomed circumstances, such as in a bed, in a parent's arms, or while being fed. These sleep-onset associations may begin in the first 2 months of life and are one of several behavioral causes for insufficient sleep outlined in Table 194-4. Sleep-onset association may be viewed as a problem by the family when a child older than 6 months needs prolonged parental assistance to fall asleep at the beginning of the night and after each nocturnal arousal. This pattern is a conditioned response, and the child is unable to fall asleep unless the conditions allowing sleep onset are recreated. Parents may complain that their own sleep is severely disrupted because they need to help the infant resettle several times each night. Treatment is straightforward—the child learns to make the transition from wake to sleep without expecting a parent's participation. Parents should be advised to place the infant while still awake into the crib for both night and naps starting by 48 weeks postgestational age. A helpful tactic is for the infant's bedding to have the mother's scent for comfort. If a problematic sleep-onset association has already developed, then parents may

**Table 194-4** Causes of Insufficient Sleep in Children

	PREVALENCE	TREATMENT
<b>BEHAVIORAL</b>		
Sleep-onset association disorder	30%–40%	Education, extinction strategy
Limit-setting disorder		Education, family counseling
Adjustment disorder		Education, family counseling
Chronic sleep deprivation	Common	Education in sleep hygiene
Early school starting times		Education; advocacy (petition school boards and legislature for later school start times)
Parent work schedule		Education
Social activities		Education
Idiopathic insomnia (diagnosis of exclusion; often made retrospectively)	Unknown	Good sleep hygiene; hypnotics under investigation
Circadian rhythm disorder		Education, morning light therapy
Delayed sleep phase		Advance sleep phase

need to institute a graduated extinction program (see below) to help infants older than 6 months learn to fall asleep on their own over several weeks.

Although graduated extinction is a very effective treatment, parental distress is a common issue during the initial portions of employing an extinction strategy. Warning parents what to expect and addressing fears about harming or creating a sense of abandonment in the child may alleviate some parental concern. Successful treatment will require consistency, and it is important that all nighttime caregivers are able to implement the extinction technique. If the parents are uncertain that they will be able to consistently implement extinction strategy, it may be advisable to delay treatment until that is possible. Parents should be educated that the extinction process may take longer if the disruptive sleep pattern becomes more well-established as the child becomes older.

### Limit-Setting Disorder

Bedtime routines should take 30 minutes or less. Consistently longer bedtime routines may reflect parental difficulty in setting limits. Prolonged bedtime routines are often associated with multiple curtain calls for stories, hugs, water, and trips to the toilet. Toddlers and preschool children no longer sleeping in a crib may reappear after being put to bed, thus prolonging the routine. These curtain calls are unintentionally reinforced by the parental attention needed to return the child to bed, even if done with obvious displeasure.

The best management of prolonged bedtime routines is prevention through reasonable daily schedules, assurance of adequate special individual time with each parent every day, and careful limit setting. This approach reduces the child's separation anxiety as well as parental guilt. The bedtime routine should be limited to a defined set of activities or length of

time. Parents may then either notify the child that they will not respond to further requests, or say "only one more" and adhere to this declaration. Parents should be warned to avoid responding to the excuses that will likely ensue. Having the parent promise to check the child frequently can also be reassuring. Bedtime should occur when the child is tired to enhance his or her tendency to fall asleep. Naps should not occur close to bedtime.

Positive reinforcement may enhance limit setting. Children who stay in bed without calling out may be motivated by simple rewards with stickers in the morning or an extra story the following night. Parents may need coaching on limit setting or referral to a psychologist if discipline is a major problem, or they may benefit from marital counseling if significant discord exists regarding family life.

### Bedtime Fears

Preschool and early school-aged children often have bedtime fears, which are often generated by stresses such as separation from parents, aggressive peers, sibling birth, or the death of a grandparent. Exposure to frightening movies or video games can also contribute. The child's fears should be acknowledged, and he or she should be reassured that the parents will keep him or her safe. A ritual of the adult *spraying for monsters* may be helpful. Having the child help the parent buy a special flashlight to check out the room at night provides a sense of mastery. Older children benefit from relaxation exercises accompanied by empowerment stories. A nightlight may be helpful.

### Primary Insomnia

Primary insomnia can be seen in normal children but is generally transient and is a diagnosis of exclusion.

### BOX 194-2 Symptoms and Signs of Inadequate Amount of Sleep

1. Excessive daytime sleepiness (rare in young children)
2. Hyperactivity–impaired attention
3. Poor school performance–impaired concentration, vigilance
4. Behavior problems–bad mood, irritability
5. Obesity–possible link to inadequate sleep
6. Failure to thrive

It must last at least 1 month, interfere significantly with functioning or cause significant distress, and not be part of another medical, sleep, or mental disorder. The symptoms and signs of inadequate sleep are listed in Box 194-2.

Medication for primary insomnia in healthy children is controversial, but medications such as diphenhydramine, clonidine, and melatonin have been used in pediatric insomnia. Indiscriminate medication use can mislead physicians and families about the causes of insomnia and ignore the behavioral management needed.

A disruptive sleeping environment may cause either sleep onset or sleep maintenance insomnia. Excessive noise or light, uncomfortable bedding, excessive room temperature, interference of pets, or outside noises are commonly found. Treatment is simply to eliminate or correct the environmental condition or distraction.

### Other Difficulties Falling Asleep

Dyssomnia, the term for insomnia that does not meet disorder criteria, occurs mainly in preschool-aged and older children. This problem includes environmental sleep disorder caused commonly by noise, pets, and temperature extremes. Revising the household routine to allow quiet for adequate sleep is necessary to resolve this dilemma (Table 194-5).

### Awakenings From Sleep

Waking at night occurs in more than 80% of children and, of course, in infants who still need to feed. Night waking is only problematic when the child cannot return to sleep on his or her own. As many as 20% of 2-year-olds, 14% of 3-year-olds, and 6.5% of 5- to 12-year-olds have problematic night awakenings. Common causes and treatment of sleep fragmentation and disrupted sleep continuity are outlined in Table 194-5.

### Sleep-Onset Association Disorder

**TRAINED NIGHT FEEDING.** In Western industrialized societies, between 60% and 70% of either breastfed or bottle-fed infants are reported to be settling or sleeping through the night by 12 weeks of age without any specific behavioral interventions. Nonetheless, some infants older than 6 months who wake up during the night are immediately fed to encourage their return to

sleep. Their sleep cycle may be changed by the introduction of food to produce an arousal—basically, learned hunger—and they will consume a full feeding during the night. Trained night feeding should generally not be diagnosed before 6 months postterm because of the frequent need for a feeding during the night in younger or premature infants. Infants who learned to sleep through the night and subsequently begin waking during the night and seem genuinely hungry are probably ready for solids (if they are older than 4 to 6 months) or need increased volumes or number of feeds during the day and evening if they are formula fed. Breastfed infants may respond better to more frequent evening feedings (cluster feeding) of smaller but richer (higher lipid content) human milk.

Trained night feeding can be prevented by teaching parents ways to recognize when an infant is fussy because of hunger and when fussiness arises from other causes, such as boredom. Parents should not automatically feed a fussy infant unless the infant appears hungry. Parents who go to their infants older than 4 months at the first sound of stirring should also be encouraged to allow their infants the opportunity to return to sleep without intervention. Expectations of the appropriate need for a late (eg, 10:00 pm) feeding should be clarified. Daytime feeding intervals can be adjusted gradually and any sleep associations retrained simultaneously. If night feedings are an established pattern, then the formula-fed infant can be fed 1 oz less each night. This tactic will usually help resolve trained night feeding in approximately 1 week.

**TRAINED NIGHT WAKING.** Waking at night without requiring a feeding in the infant between 4 and 8 months of age is called *trained night waking*. This pattern often begins when the infant is ill or subjected to travel or some other change in routine, but the pattern may persist because the child gets a secondary reward from the parent's attention. One parent may believe that quieting the infant quickly is necessary to avoid disturbing other family members or neighbors. In some instances, parents who have little time to spend with the child during the day enjoy this time with the child and reinforce the night waking by playing with him or her. Trained night waking is also increasingly common in infants who have difficult temperaments.

Management of trained night waking that causes persistent family disruption requires management of the precipitant stress and, ideally, collaboration with the spouse or neighbors to tolerate some crying during the treatment. Bedtime routines need to be established, perhaps with bedding or infant clothing with a maternal scent, and the infant should be put into bed awake. Daytime naps should be limited to 2 hours to consolidate the longest sleep period at night. When awakening during the night, the infant should be allowed 1 to 2 minutes of crying before being checked, but not fed, and then checked every 2 to 5 minutes in most circumstances. The infant may be touched but not picked up, rocked, or cuddled. For success, this approach may require the more involved parent to take a shower, turn up music, or find some other distraction. Brief sedation with diphenhydramine for the

infant should rarely be needed to help modify this habit if the graded extinction techniques described previously are strictly applied.

**DEVELOPMENTAL NIGHT WAKING.** Although most infants are sleeping through the night by 6 months of age, many begin awakening again around 8 to 10 months of age. This new behavior, called *developmental night waking*, corresponds to several coincident developmental processes, including increased mobility, fear reactions to strangers, and object permanence (ability to remember and seek something or someone, like a parent, that is out of sight).

The best management is advising parents at the 6-month well visit to expect a recurrence of night waking. Because of differences in cultures, not all parents will see this circumstance as a problem. For parents who do, they should be advised to wait a few minutes before going to the infant but to avoid feeding or other reinforcement. If waking is already established, then the parents should have the contributing developmental forces explained and be advised to create a bedtime routine, including a transitional object and a dim nightlight. When the infant awakens, he or she should be given at least 2 minutes to self-soothe, with some fussing tolerated as part of the process. If fussing continues, then one parent can go to reassure the child briefly, without touching or feeding, and settle down within sight to sleep the rest of the night without talking to the child. The child often becomes enraged instead of fearful, which is more tolerable to the

parent, who can see that the child is safe. Some parents are more comfortable than others with this plan. For children who are no longer constrained to a crib, the parent must prevent body contact with the child by giving him or her the alternative that the parent will leave the room to avoid establishing a sleep association. Further interactions should be brief and minimally interactive. Eventually, the child will no longer require the parent's presence to return to sleep after nocturnal awakenings.

### **Sleep-Related Breathing Disorder**

The pediatrician is often confronted with the problem of what to do with the child who snores. Snoring is common; OSA is less common.

Young children with SDB are usually not obese, unlike typical adult patients. Some groups of children are at particularly high risk for SDB, including those with craniofacial anomalies, chromosomal syndromes, and neuromuscular disorders. Children with Down syndrome, Prader-Willi syndrome, cleft palate, achondroplasia, muscular dystrophy, cerebral palsy, and other underlying disorders should be routinely screened for sleep problems. Although children with Down syndrome, for instance, typically have learning difficulties, treatment of SDB may result in improved daytime performance.

While many children with obstructive SDB improve after adenotonsillectomy, those with either obesity or asthma are more likely not to have complete resolution

of symptoms. On occasion, nasal continuous positive airway pressure (CPAP) or even tracheostomy may be required.

The question of whether all children should have sleep studies before undergoing adenotonsillectomy is controversial. However, certain groups of children are clearly at higher risk for perioperative complications and may warrant polysomnograms as part of a preoperative evaluation, especially if outpatient surgery is being contemplated. Children younger than 3 years, children with morbid obesity or chromosomal or craniofacial anomalies, children with underlying neuromuscular disorders, and those with other underlying medical conditions that make them higher-risk surgical patients should be considered for preoperative polysomnograms.

### **Circadian Rhythm Sleep Disorder**

The most common circadian rhythm disorder causing insomnia is a sleep-phase delay that is commonly seen in adolescents. Because the natural circadian cycle is approximately 24.5 hours, some individuals are vulnerable to shifting sleep cycles by approximately 30 minutes a day. This shift often results in difficulty waking in time for school in the morning. Morning battles with parents about waking for school are common. Phase-delayed adolescents often sleep very late on weekends and vacations and then find falling asleep at a reasonable bedtime even more difficult. Changing adolescent sleep-phase delay is very difficult and requires intense commitment and active participation of the adolescent and parents with the use of bright light exposure in the morning and consistent wake times all 7 days of the week.

Some children who are deprived of normal circadian stimuli develop circadian rhythm disorders. Because zeitgebers that entrain normal circadian rhythm include light (especially sunlight that may be 100,000 lux), exercise, social activities, and eating, the fact that a child with cerebral palsy who is blind, wheelchair dependent, and fed by gastrostomy tube has difficulty with a varying sleep time is not surprising.

Other children have circadian rhythm problems that reflect a chaotic home life. Some families do not adhere to predictable routines, allowing children to set their own schedules, resulting in seemingly bizarre sleep patterns. A circadian rhythm disorder may be differentiated from an oppositional disorder by the child's behavior pattern. A child with a circadian rhythm disorder may not resist going to bed but is unable to fall asleep. In the morning, the child is difficult to arouse and does not feel rested.

A sleep-phase advance usually occurs in infants or toddlers who fall asleep early (7:00 pm) but then awaken early in the morning (3:00 am). Different types of circadian shift can be adjusted by simultaneously shifting naps, bedtime, waking time, and meals to a desired schedule that matches the child's total daily sleep needs.

In difficult cases, the child can wear an actigraph, a small portable device similar to a large wristwatch, for several weeks. The device senses physical motion by means of an accelerometer and stores the information. Actigraphy provides a graphic illustration of a child's

sleep-wake schedule and can be a useful, noninvasive method for assessing specific sleep disorders such as insomnia, excessive daytime sleepiness, and circadian rhythm disorders (Figure 194-2).

### **Parasomnias (Partial Arousal Disorders)**

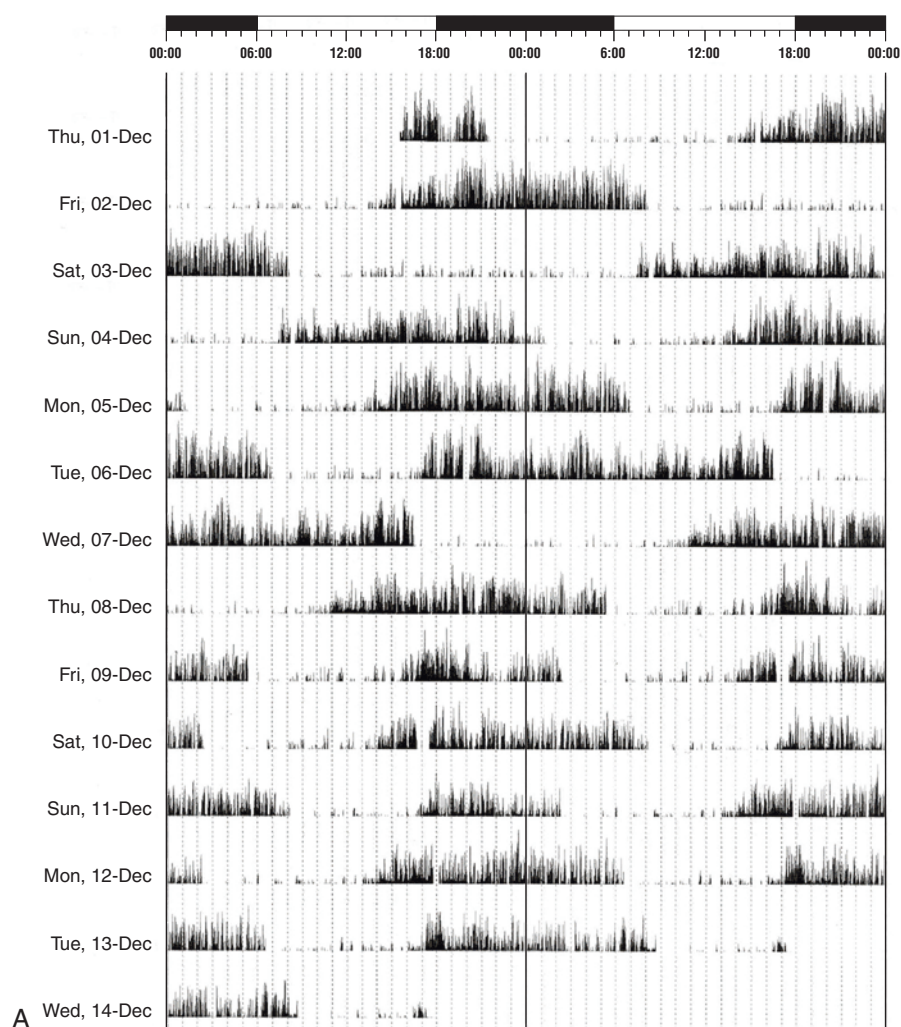

Parasomnias are unusual behaviors or experiences that occur during sleep or the transition between sleep and wake. Parasomnias associated with partial arousal from slow-wave sleep are common in children. They include confusional arousals, sleep terrors, and sleepwalking disorder (somnambulism). All of these episodes occur during arousal from slow-wave sleep, usually in the first third of the night. The child appears confused or frightened and is unresponsive to parental intervention. The child is not fully awake and does not remember the event in the morning.

Symptoms most often begin in childhood and resolve spontaneously, occasionally persisting into adulthood (0.5%). Diagnosis is based on the timing of these symptoms (generally during the first third of the night), the typical presentation, and the child's lack of recall of the events when awake the next morning (morning amnesia). A strong familial component exists, and history often reveals that one or both parents had similar behaviors as children.

**CONFUSIONAL AROUSALS.** Young children may experience partial arousals from slow-wave sleep, during which they sit up, mumble, and may appear awake; they seem confused and nonresponsive to parental questions. The prevalence of confusional arousals was 17% between ages 3 and 13 years in one study. Children may sometimes thrash about and respond combatively to parental attempts to intervene. Confusional arousals usually occur in the first third of the night, but a child may occasionally have multiple arousals, extending into the second half of the night, generally decreasing in intensity. Confusional arousals are most common when children are overtired or ill. Management includes reassurance that the episodes are generally benign, minimal intervention during episodes, and removal of potential safety hazards from the child's bedroom. Treating disorders that may fragment sleep such as OSA and restless leg syndrome can be helpful. In severe cases, a few weeks of a benzodiazepine, such as lorazepam, at bedtime may interrupt the sequence by reducing slow-wave sleep. However, rebound occurs with discontinuation of the medication, often with an increasing number of events. A sleep study may help to confirm the diagnosis and detect precipitating events such as OSA or nocturnal seizures in severe or atypical cases.

**SLEEP TERRORS.** Sleep terrors are partial awakenings from slow-wave sleep characterized by physiologic arousal including pallor, sweating, pupillary dilation, piloerection, and tachycardia. The child may sit up and scream and may appear terrified. The child may thrash or run and is not responsive to attempted parental comforting. The child does not remember the event in the morning. Sleep terrors occur in 3% of children, usually starting between 18 months and 5 years. These episodes do not reflect emotional disturbance, although, as with all NREM parasomnias, occurrence is increased with illness,

**Figure 194-2** Ten-year-old child with Down syndrome and nighttime G-tube feeding after brain injury. A, Random sleeping pattern with the child frequently awake at night.

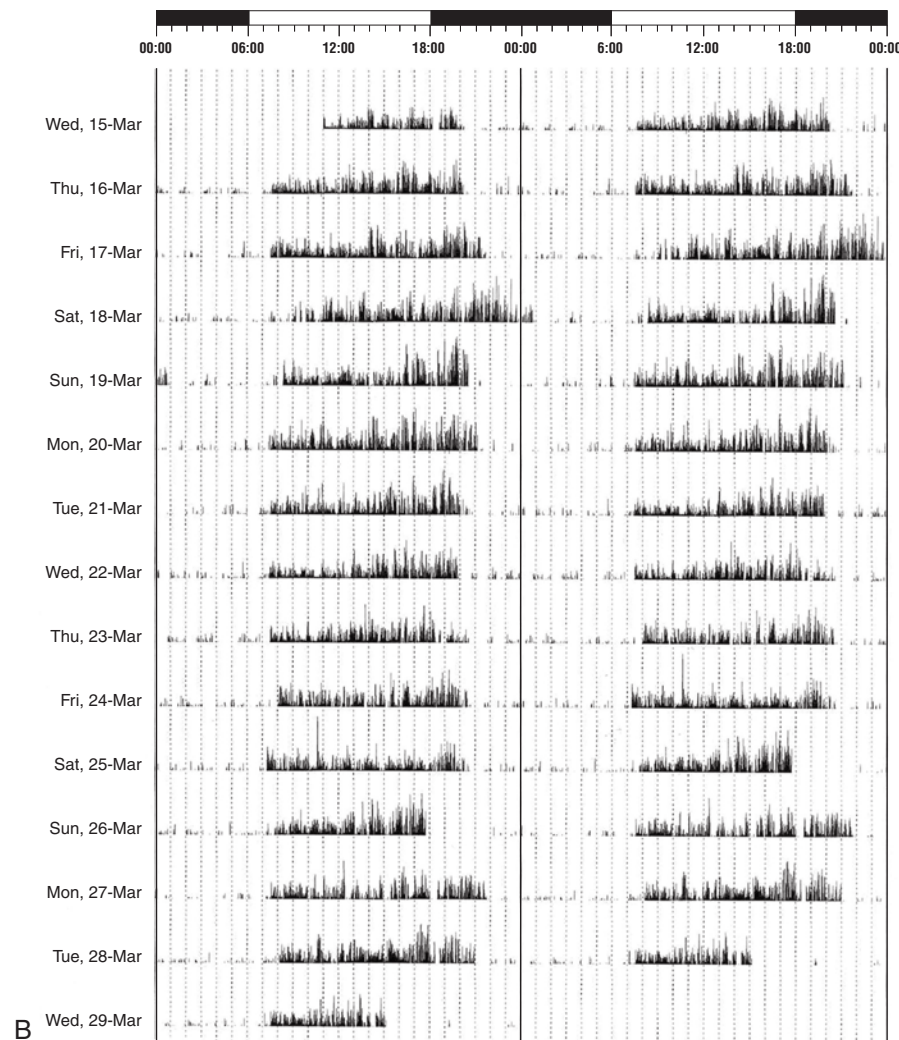

stress, or sleep deprivation. A family history of sleep terrors, enuresis, somnambulism, or sleep talking is often present. Sleep terrors may be precipitated by fatigue, stress, a full bladder, or loud noises. They tend to occur in bouts for several weeks and then disappear only to recur several weeks later. Parents need reassurance about the benign nature of sleep terrors and their tendency to resolve in approximately 95% of children by 8 years of age. The bladder should be emptied routinely before bedtime, and the environment should be kept dark and quiet. The bouts may occasionally be interrupted by waking the child 15 minutes before the expected episode, generally occurring approximately 1 hour into sleep each night for approximately a week. A 30- to 60-minute afternoon nap can also reduce the depth and amount of stage IV sleep and may decrease the number of episodes. Treatment with benzodiazepines can reduce the frequency of these events by altering slow-wave sleep, but episodes may recur when the child is weaned or when tolerance occurs. An investigation for nocturnal

seizures with full EEG as part of a sleep study is indicated in intractable cases or those that have their onset in adolescence.

#### **SLEEPWALKING DISORDER (SOMNAMBULISM).**

Approximately 15% of children sleepwalk at some time. Between 1% and 6% have 1 to 4 episodes per week, mostly between ages 4 and 12 years. Sleepwalking, as with other disorders of arousal, occurs mainly during slow-wave stage N3 sleep, generally in the initial 120 minutes of sleep. During sleepwalking, children are difficult to arouse, are uncoordinated, and tend to wander in illogical places, often urinating outside the toilet. Chronic sleepwalkers need to be carefully safeguarded so that they do not injure themselves. Door and window alarms and locks may be necessary. Amnesia of the event in the morning is common. Sleepwalking can usually be differentiated by history (regular timing, same movements) or videotapes from dissociative states or seizures; however, occasionally, extended EEG as part of a sleep study may be necessary.

**Figure 194-2, cont'd** B, Stabilized sleeping pattern using nighttime melatonin and morning phototherapy, and stopping G-tube feedings at night.

### Nightmare Disorder

Nightmares are an extremely common parasomnia occurring during REM sleep and are most common in the last third of the sleep period. The dream content often is recalled as frightening and reflects daytime stresses. Although children clearly dream by 14 months of age, nightmares are most common between 3 and 6 years, occurring in 10% to 50% of children. At these ages, children have the verbal skills to describe dreams. They also have vivid imaginations and fears.

Nightmares are uniformly part of posttraumatic stress disorder; they may increase after withdrawal of REM-suppressing substances such as alcohol and antidepressants.

A child who wakes from a frightening dream should be comforted, keeping the intervention brief to avoid secondary gain. The same concerns listed for bedtime fears should be addressed when nightmares are frequent. Children who have chronic nightmares have been shown to improve with targeted relaxation

exercises and stories in which the child masters a situation. Children can prepare to have good dreams through rehearsal and imaging at bedtime. Severe nightmares may respond to bedtime medications, although counseling is mandatory if the condition is of a severity to warrant medication.

### Violent Behavior During Sleep

An REM behavior disorder (RBD) has been described in which normal REM atonia does not occur. Dream content can be physically acted out, sometimes in violent ways. RBD is very rare in healthy children but has been seen in autistic children or in association with neurologic disorders. A clue to diagnosis is that abnormal behaviors occur during the last third of the night, unlike NREM motor parasomnias, which typically occur during slow-wave sleep during the first third of the sleep period. Diagnosis requires a sleep study and neuroimaging studies. Treatment with

clonazepam has been beneficial in autistic children and is the most common treatment in adults.

### Other Parasomnias

Bruxism is grinding the teeth during sleep and has been reported in more than 50% of children, with a mean age of onset of 10.5 years. No longitudinal studies demonstrating the natural history of bruxism have been conducted, but dental evidence of bruxism can be identified in 10% to 20% of the general population. Bruxism can also be caused by dental malocclusion or neurologic or psychiatric conditions. Tooth guards can protect the teeth and reduce potential damage to the temporomandibular joint. If stress or anxiety is a trigger, then relaxation exercises at bedtime may be helpful.

## SLEEP-RELATED MOVEMENT DISORDERS

### Restless Legs Syndrome and Periodic Limb Movements of Sleep

Restless legs syndrome occurs in about 2% of children between 8 and 17 years of age. It is characterized by uncomfortable sensations in the legs, which are worse at rest (“like worms crawling under my skin”). These sensations are present in the evening, are associated with the need to move, and are temporarily relieved by movement. They are sometimes confused with growing pains. They may interfere with the child’s ability to fall asleep. A strong familial component exists. Periodic limb movements of sleep are repetitive, brief leg twitches, occurring more than 5 times per hour in children. Leg movements or jerks may occur with resumption of a breath after a central apnea or with a loud snort or snore at the termination of an obstructive apnea. They may cause arousals, fragmenting the continuity of sleep and leading to a complaint of sleep maintenance insomnia. Although the two syndromes are not identical, many patients

experience both. In children, limb movements may be exacerbated by iron deficiency or the use of antidepressant medication. They are more common in children with attention-deficit/hyperactivity disorder (ADHD). Treatment may include iron supplements, clonidine, gabapentin, or dopaminergic agents, depending on the age of the child.

### Sleep–Wake Transition Disorder

Rhythmic movements while falling asleep are common in infants and toddlers. Rhythmic movement disorders include head banging and body rocking. Some rhythmic activity at bedtime occurs in more than half of 9-month-olds, decreasing to one-third at 18 months, and to less than one-fourth at 2 years of age. Head banging is typically monotonous, occurring 60 to 80 times per minute, usually for less than 15 minutes. Usually benign, head banging may occasionally be caused by CNS injury, headache, inner ear abnormality, sensory deprivation (including visual or hearing impairment), neglect, or abuse. Children of intense temperament are especially likely to bang. Although head banging usually does not cause brain injury, it can be traumatic if the bed is unstable or if safety precautions are not taken in the environment. The condition may be reduced by kinesthetic stimulation during the evening and holding the child as part of the bedtime routine. Sleep restriction (ie, limiting the time the child lies in bed before falling asleep) and mild sedation have been shown to be helpful in difficult cases. Parents often need reassurance of the generally benign nature of these behaviors.

## HYPERSOMNIA

Excessive daytime sleepiness (EDS) can be caused by insufficient sleep (see Table 194-4), fragmented sleep (see Table 194-5), or increased sleep drive (Table 194-6). Although some sleepy children appear to have difficulty remaining awake, many sleepy children may exhibit hyperactivity, restlessness, poor concentration,

impulsivity, aggressiveness, or irritability. Sleepiness needs to be differentiated from weakness or fatigue. The major sleep disorders causing primary hypersomnia in children are narcolepsy and idiopathic hypersomnia.

### Narcolepsy

Narcolepsy is a potentially disabling syndrome of irresistible daytime sleep attacks, abnormally fast transitions to REM sleep from awake, and disrupted nighttime sleep. It occurs in 0.04% of whites and 0.07% of blacks. As many as one-third of adults with narcolepsy report onset of symptoms before 15 years of age, but diagnosis is frequently delayed at least a decade. Loss of muscle tone with emotions while awake (cataplexy), inability to move for a few seconds to minutes on awakening (sleep paralysis), and visual aura or dream states while falling asleep (hypnagogic hallucinations), along with EDS, make up the complete narcolepsy tetrad seen in 30% of affected persons. Approximately 90% of patients with narcolepsy with cataplexy are positive for HLA DQB1\*0602. Narcolepsy is seen in children, but peak age of onset of symptoms is 15 to 25 years. Cataplexy—brief episodes of bilateral muscle weakness, usually associated with laughter or strong emotion, that may result in falling, head bobbing, or jaw sagging—is highly specific to narcolepsy but may not be seen in more than 50% of cases. Diagnosis of narcolepsy without documented cataplexy can be made by overnight polysomnography showing absence of other sleep diagnoses and a multiple sleep latency test (5 nap opportunities, separated by 2 hours, immediately following the overnight sleep study) showing rapid sleep onset periods (mean, <8 minutes) with at least 2 naps containing REM sleep. Differential diagnosis includes hydrocephalus, postviral infection (mononucleosis), previous CNS trauma, or idiopathic hypersomnia. Absence of HLA DQB1\*0602 does not exclude the diagnosis of narcolepsy, especially without cataplexy. Given that 20% of the general population is positive for HLA DQB1\*0602, this test is not specific for possible narcolepsy patients with EDS. Recent research shows that narcolepsy with cataplexy results from the loss of approximately 70,000 hypothalamic neurons producing the neuropeptide hypocretin.

Narcolepsy treatment may include the use of stimulants such as modafinil or methylphenidate to address excessive daytime sleepiness, antidepressants such as venlafaxine to control cataplexy, regular adequate sleep, 2 to 3 planned 30-minute daytime naps, and timing of activities at optimal hours of alertness. Education of the patient, family members, and school personnel is important. Support for handling the difficulties of this lifelong chronic condition is such that referral to a pediatric sleep disorders center is indicated, but often primary care physicians may be required to monitor compliance with medications for participation in activities such as sports, school testing, and driving.

### Idiopathic Hypersomnia

Idiopathic hypersomnia is a disorder of constant and severe EDS, despite adequate nocturnal sleep.

Idiopathic hypersomnia is, by definition, a diagnosis of exclusion. A complete evaluation for other causes of hypersomnia must be undertaken, including neurologic disorders (hydrocephalus or CNS tumors), primary sleep disorders (OSA), mood disorders, chronic fatigue syndrome, and medical disorders (acute and chronic infections including mononucleosis, metabolic disorders, or muscle diseases). Although the mean sleep latency is short in idiopathic hypersomnia, similar to narcolepsy, affected patients do not have the 2 sleep-onset REM periods that characterize narcolepsy. Treatment of idiopathic hypersomnia includes attention to sleep hygiene issues, use of stimulant medications, and thorough review of safety issues such as driving or operating machinery.

## SLEEP DISORDERS ASSOCIATED WITH PSYCHIATRIC OR BEHAVIORAL DISORDERS

Although sleep problems may occur in association with almost any mental health disorder (Table 194-7), mood disorders are among the most common. Depression may cause sleep-onset insomnia, although this condition is less common in young children than in other age groups. The early-morning waking of depressed adults is not usually seen before puberty and only rarely among adolescents, for whom hypersomnia is a more common complaint than insomnia. The sleep problems that are intrinsic to depression are complicated by intrusive thoughts or worries that may interfere with sleep maintenance. Treatments of sleeping problems in depressed children may include cognitive behavioral therapy and antidepressants.

Children with bipolar disorder may have a dramatically reduced need for sleep (<4 hours a day) during the manic phase. Anxiety and panic disorders may result in difficulties falling asleep because of specific or nonspecific fears, as well as difficulties returning to sleep if aroused during the night. Children who have been abused have frequent sleep problems, including nightmares, increased activity during sleep, and sleep-onset and sleep-maintenance insomnia.

Personality disorders in adolescence have been associated with sleep-onset insomnia. Psychoses may include troubling intrusive thoughts, especially at night.

Insomnia or hypersomnia caused by substance abuse should be considered in sleep disorders in older children and adolescents. Alcohol can induce sleep, but it causes sleep fragmentation in the latter portion of the night. When alcohol is metabolized (1 beer, 5 oz of wine, or 1 oz of liquor per hour), sympathetic tone increases, leading to abrupt arousals and sleep maintenance insomnia. Withdrawal from chronic alcohol abuse may cause severe insomnia. Stimulants such as cocaine and amphetamines can cause severe insomnia. Some antidepressants such as fluoxetine may cause insomnia, whereas others such as tricyclics, trazodone, or mirtazapine may cause EDS. Antidepressants may eliminate REM atonia, thus precipitating RBD. Atypical antipsychotics such as aripiprazole may cause stimulation, whereas others such as olanzapine cause sedation.

**Table 194-7 Behavioral and Psychiatric Disorders Associated With Sleep Problems in Children**

DIAGNOSIS	SLEEP PROBLEMS
Depression	Sleep-onset or maintenance insomnia seen in 50% Early morning awakenings EDS seen in 25% Sleep complaints are the most prevalent symptoms of major depression in adolescents
Bipolar disorder	Decreased need for sleep without fatigue Insomnia
Seasonal affective disorder	Prevalence 3%–4% in children with EDS, fatigue in winter
Anxiety disorder	Increased night awakenings, nighttime fears Increased sleep-onset insomnia, bedtime problems Increased EDS
Obsessive compulsive disorder	Decreased total sleep time
Autism, pervasive developmental disorder	Sleep-onset insomnia, difficulty settling at night, prolonged and frequent nocturnal awakenings Shortened duration of sleep Irregular sleep–wake pattern Parasomnia (including rapid eye movement behavioral disorder)
Attention-deficit/hyperactivity disorder	Sleep-onset or maintenance insomnia Nocturnal waking, obstructive sleep apnea, excessive periodic limb movements

EDS, excessive daytime sleepiness.

Derived from Ivananko A, Crabtree VM, Gozal D. Sleep in children with psychiatric disorders. *Pediatr Clin North Am.* 2004;51:51–68.

## DEVELOPMENTAL DISORDERS

Learning disabilities are associated with increased rates of sleep disturbance, including night waking and trouble falling asleep. Half of these sleep difficulties persist for more than 3 years. Systematic review of the literature suggests that children with ADHD have higher daytime sleepiness, more movements during sleep, and higher apnea-hypopnea indexes compared with controls. Reported sleep problems also include trouble settling to sleep and multiple awakenings from sleep. Medications used to treat ADHD may prolong sleep-onset latency. Clonidine at bedtime has been found to be effective in improving the sleep of 85% of these children when behavioral measures failed.

Many children with autism have serious sleep problems, with difficulties falling asleep, waking in the night, and early-morning waking. Children with autism frequently have insomnia that may benefit from behavioral interventions, melatonin, or medications. Asperger syndrome has been associated with insomnia and RBD. Children who have Tourette syndrome have increased parasomnias.

## SLEEP DISORDERS ASSOCIATED WITH MEDICAL PROBLEMS

Sleep problems are seen in a variety of medical conditions (Table 194-8).

### Neurologic Disorders

Any CNS impairment can result in dysregulation of the sleep cycle. As many as 85% of children who have major developmental disabilities may experience chronic sleep problems. Behavioral sleep problems in these children can be improved by establishing a

bedtime routine and putting the child to bed when sleep onset is likely to occur quickly. If the child has persistent difficulty falling asleep, then establishing a new pattern may be helpful by delaying the usual bedtime for 30 minutes and then removing the child from bed if sleep does not occur in 15 to 20 minutes. After removing the child from bed, the parent should keep him or her awake for 30 minutes. This procedure is repeated until the child falls asleep within 15 minutes of being put in bed. Wake-up time is kept constant. Daytime naps are not allowed for children older than 4 years.

Other factors such as timing of medications, need for repositioning during the night, pain, nighttime feedings, and caregiver anxiety can contribute to sleep problems in the neurologically impaired child. Melatonin at bedtime has been shown to be helpful in some children who have CNS problems or blindness as the cause of their sleep disturbance. Melatonin should be used cautiously in children with seizure disorders.

Kleine-Levin syndrome, a rare disorder with episodes of severe daytime sleepiness, hyperphagia, and hypersexuality lasting hours to weeks, may be seen in adolescence. Tumors of the third ventricle or posterior hypothalamus may also cause daytime sleepiness. Brainstem lesions or Chiari malformation type II, which are common in children with myelomeningocele, can cause severe central apnea or vocal cord paralysis causing obstructive apnea.

### Sleep-Related Epilepsy

Approximately 20% of epileptic patients have seizures only during sleep, most often at the time of sleep–wake transitions. Seizures occurring during the night may disrupt sleep by causing multiple awakenings.

**Table 194-8** Medical Disorders Associated With Sleep Problems in Childhood

DIAGNOSIS	SLEEP PROBLEMS
Asthma	Circadian variation in <ul style="list-style-type: none"> <li>• Peak expiratory flow (nadir at 4:00 am)</li> <li>• Cutaneous immediate hypersensitivity to house dust allergen</li> <li>• Airway inflammation</li> </ul> Sleep-related changes <ul style="list-style-type: none"> <li>• Decrease in lung volumes and increase airway resistance</li> <li>• Increase airway resistance and decrease intrapulmonary blood volume</li> <li>• Decrease mucociliary clearance</li> <li>• Nocturnal gastroesophageal reflux</li> </ul> Frequent nocturnal awakenings and decrease stage 4 sleep
Cystic fibrosis	OSA can be common in children <7 years. Nocturnal oxygen desaturation in children >7 years <ul style="list-style-type: none"> <li>• Hypoventilation, especially in REM sleep caused by de-recruitment of ventilatory muscles</li> <li>• Ventilation-perfusion mismatch caused by decreased functional residual capacity</li> <li>• Occurs more frequently with forced expiratory volume &lt;65% or resting oxygen saturation while sitting &lt;94%</li> </ul>
Craniofacial abnormalities (Pierre Robin sequence, Goldenhar syndrome, Down syndrome, Treacher Collins syndrome, velocardiofacial syndrome, cleft lip and palate)	Upper airway obstruction Nocturnal hypoventilation
Gastroesophageal reflux	Increased night awakening and pain Delayed sleep onset May result in nocturnal stridor, cough, and wheezing
Down syndrome	Upper airway obstruction with OSA in 30%–60% Decreased REM sleep associated with low IQ
Sickle cell disease	Episodic and continuous nocturnal hypoxemia in 40% of children caused by either OSA or primary lung disease
Obesity	OSA <ul style="list-style-type: none"> <li>• Obesity hypoventilation syndrome: Hypercapnia, hypoxemia, and daytime somnolence.</li> <li>• 95% of children with Prader-Willi syndrome have excessive daytime sleepiness.</li> </ul>
Scoliosis or congenital neuromuscular disorder (Duchenne muscular dystrophy, spinal muscular atrophy)	Nocturnal hypoventilation Nocturnal hypoxemia—excessive daytime sleepiness, morning headaches OSA Restless sleep Frequent awakenings
Traumatic brain injuries	Sleep-onset and maintenance insomnia Excessive daytime sleepiness Dreaming disturbances Nocturnal hypoventilation
Spina bifida	Obstructive, central, or mixed apnea Nocturnal hypoventilation may cause severe excessive daytime sleepiness

OSA, obstructive sleep apnea; REM, rapid eye movement.

Derived from Bandla H, Splaingard M. Sleep problems in children with common medical disorders. *Pediatr Clin North Am.* 2004;51:203–227.

The possibility of a seizure disorder should be considered in adolescents with new-onset parasomnias. Atypical seizures may produce EDS.

### Sleep-Related Headaches

Most headaches occurring during sleep occur during REM sleep. Cluster headaches are more frequent at night than in the daytime and often disrupt sleep. Headaches on awakening are unusual; the child should be evaluated carefully for the presence of increased intracranial pressure or hypercapnia caused by hypoventilation (eg, Duchenne muscular dystrophy).

### Degenerative Disorders

Degenerative brain disorders result in frequent awakenings, difficulty falling asleep, early-morning waking, sleep deprivation, and daytime sleepiness.

### Other Medical Disorders

Any condition causing pain at night, such as juvenile idiopathic arthritis, can result in disrupted sleep. Eczema that causes associated scratching results in frequent awakenings. Painful menstrual cramps may also disrupt sleep.

### Sleep-Related Asthma

Asthma episodes are increased during sleep, presumably because the neuroendocrine regulators of respiration are sensitive to diurnal regulation. Children who have sleep-related asthma have fragmented sleep and may develop anxiety associated with breathing discomfort. This disruption may lead to bedtime resistance and insufficient nocturnal sleep, leading to problems outlined in Box 194-2. In one study of children with asthma, 34% awakened at least once a week, and 5% awakened every night from asthma symptoms. Daytime sequelae were common, with 59% reporting daytime sleepiness and 51% reporting difficulty with concentration. These complaints all improved with successful asthma management.

### Gastroesophageal Reflux Disease

Gastroesophageal reflux disease (GERD) may produce sleep problems in a variety of ways. The reflux can be painful, resulting in night waking and crying. Reflux has also been associated with both central and obstructive apnea and with apparent life-threatening events in infants and young children. The diagnosis of GERD may not always be obvious, owing to lack of usual signs, including excessive spitting up, reswallowing motions, increased fussiness, refusal of feedings, and failure to thrive. Esophagoscopy, assessing for esophageal erosions, may be needed to determine the cause of nighttime pain. Failure to be consoled while being held can be a clue that the child is suffering pain. Holding the child upright reduces the amount of acid in the esophagus and may comfort a child with reflux. See Chapter 206, Vomiting, for further discussion of gastroesophageal reflux.

#### WHEN TO REFER

- If the physician is unable to relieve a sleep disturbance after working with the family over the course of 6 weeks, then assistance may be needed either from a sleep specialist or from a family therapist or psychologist. The physician should always consider, and generally respect, a family that really does not care to change a sleeping situation that would seem to be a sleep disturbance to others. Children with chronic, physically based sleep disorders, such as narcolepsy and SDB requiring CPAP, benefit from referral to a sleep disorders center for treatment and group support.
- Alternative therapies have been devised by many cultures to restore the essential health-giving function of sleep. Herbal remedies such as chamomile and other soothing teas are common. Any treatment that involves scheduled rest and mental preparation for sleep would be expected to result in improvement.

#### WHEN TO ADMIT

- Primary sleep disturbances rarely require hospitalization, other than the overnight stay needed for a sleep study. Exceptions may include severe SDB with life-threatening oxygen desaturations,

arrhythmias, or cor pulmonale. Hospitalization may be needed for some of the underlying disorders, such as CNS tumors or serious depression that may initially present symptoms of a sleep disorder. Admission for video EEG monitoring of movements during sleep that suggest seizures may be required.

**Chapter 195****SPEECH AND LANGUAGE CONCERNS***Maris Rosenberg, MD; Nancy Tarshis, MA, MS***INTRODUCTION**

Speech and language delay, arguably the most common developmental concern parents have about their young children, occurs with an estimated prevalence of 2% to 19%. The delay can occur alone, or signal the presence of other developmental disorders such as intellectual disability, autistic spectrum disorders, or hearing impairment. In keeping with the recommendations of the American Academy of Pediatrics (AAP), the pediatrician should perform developmental surveillance and screening to identify children at risk, refer for appropriate evaluation, and implement intervention as early as possible. Speech and language impairments have academic, social, and behavioral implications, and appropriate intervention can maximize a child's outcome.

Parents commonly focus on their child's verbal communication and consult the pediatrician when there are concerns. A working knowledge of risk factors for communication delays, normal speech and language milestones, and red flags for language delays and associated developmental problems is essential in providing appropriate pediatric primary care.

**LANGUAGE DEVELOPMENT**

Language, as the primary vehicle for communication, is a socially shared code or conventional system for representing concepts through an arbitrary set of rule-governed symbols (speech sounds/phonemes) and symbol combinations. A social tool through which we share ideas and rules of behavior and develop our attachments to people and places, language is a rule-governed yet generative system that permits speakers to create an endless number of meaningful utterances to communicate thoughts, feelings, information, and ideas.

A summary of typically acquired speech and language milestones is presented in Table 195-1.

**RISK FACTORS FOR LANGUAGE DELAYS**

Risk factors for language delays are similar to those for developmental disorders in general. In a review for the US Preventive Services Task Force, the most common risk factors reported were a family history of speech and language delay, male gender, and perinatal factors. Other, less commonly reported risk factors included educational level of the parents, childhood illness, and family size. A careful history eliciting any prenatal, perinatal, or postnatal adverse events and a detailed family history focusing on developmental disorders, academic achievement, and social functioning are essential in determining which children are at greater risk. Environmental factors clearly play a role in determining language development. Children who live in disadvantaged environments with less language

**Table 195-1      Developmental Milestones**

AGE	DEVELOPMENTAL MILESTONES
0–6 mo	Cooing Babbling Differentiated cries
6–9 mo	Canonical babbling (reduplicated babbling, eg, “bababa”) Response to name Comprehension of familiar words in context
9–15 mo	First words Directed point (initially with hand, then with 1 finger)
18–24 mo	Uses own name 2-word sentences (by 24 mo) Knows 5 body parts
24–30 mo	Pretend play with familiar objects 3-word sentences Points to action words in pictures Answers simple, concrete “wh-” questions (eg, who, what)
30–36 mo	Uses 50+ words Names most familiar things and pictures Begins to recognize same and different Helps tell a familiar story Uses descriptive words (adjectives) Uses 200–1,000 words
3–4 yr	Speech is nearly all intelligible to any listener. Comprehends 1,000 words Points to common objects by function Responds to commands involving 2 actions Uses at least 800 words Responds to simple “how” questions Asks “what” and “who” questions Uses plurals and verb tense markers Talks about events out of the here and now
4–5 yr	Understands most of what is said to him or her Tells a personal story with a beginning, middle, and end Can listen and answer questions about a story Speech is fully intelligible. Can recognize and produce rhymes

stimulation and greater psychosocial stress are at greater risk for language delay than children from more advantaged backgrounds.

Table 195-2 states the red flags in language and play that may signal the existence of a language or other developmental disorder.

**ROLE OF THE PRIMARY CARE PHYSICIAN: SURVEILLANCE AND SCREENING**

Performing developmental surveillance at all health maintenance visits implies eliciting parental concerns, acknowledging risk and protective factors, performing longitudinal observations, and keeping an accurate, ongoing record.

The use of standardized general developmental screening instruments is recommended at ages 9, 18,

**Table 195-2** Red Flags in Language and Play

AGE	WARNING SIGNS AND RED FLAGS
0–12 mo: play	<ul style="list-style-type: none"> <li>Restricted repertoire of skills</li> <li>Does not follow objects that fall</li> <li>Little purposeful play</li> <li>Reduced or absent imitation</li> <li>Reduced object permanence</li> <li>No interactive games</li> </ul>
0–12 mo: sensory motor	<ul style="list-style-type: none"> <li>Does not reach or swat at objects</li> <li>Overly reactive to stimuli</li> <li>Extreme irritability</li> </ul>
0–12 mo: socioemotional	<ul style="list-style-type: none"> <li>Overly clingy</li> <li>No apparent attachments</li> <li>No awareness of danger</li> <li>Difficulty modulating emotions</li> <li>Reduced range of affect</li> </ul>
0–12 mo: speech and language	<ul style="list-style-type: none"> <li>Difficulty sucking and feeding</li> <li>Averts gaze</li> <li>Fails to make a variety of sounds</li> <li>Fails to respond to name</li> <li>Undifferentiated crying</li> </ul>
12–24 mo: play	<ul style="list-style-type: none"> <li>No container play</li> <li>No early problem solving</li> <li>Does not go to adults for help</li> <li>Very rigid play</li> <li>Focuses on irrelevant parts of toys such as wheels of car</li> <li>Does not include adults in play; prefers to play alone</li> <li>No interest in playing symbolically</li> <li>No spontaneous pretend play</li> <li>Restricted range of interests</li> <li>No early problem solving</li> </ul>
12–24 mo: socioemotional	<ul style="list-style-type: none"> <li>Short attention span</li> <li>Does not seek to engage with others</li> <li>Tunes out</li> <li>Avoids eye contact</li> </ul>
12–24 mo: speech and language	<ul style="list-style-type: none"> <li>No specific <i>mama</i> or <i>dada</i></li> <li>Does not point</li> <li>Cannot follow simple directives without gesture</li> <li>Reduced vocabulary</li> <li>No word combinations</li> </ul>
24–36 mo: play	<ul style="list-style-type: none"> <li>Little or no symbolic play</li> <li>Not able to sequence events in play</li> <li>Not interested in playing with peers</li> <li>Restricted range of skills and interests</li> <li>Lines up toys rather than playing with them</li> </ul>
24–36 mo: speech and language	<ul style="list-style-type: none"> <li>Avoids eye contact</li> <li>Reduced communicative intent</li> <li>Difficulty following directions</li> <li>Lack of verbal expression</li> <li>Reduced reciprocity and turn taking</li> <li>Talking better than listening</li> <li>Poor conversation skills</li> </ul>
3–4 yr: play	<ul style="list-style-type: none"> <li>Cannot take turns or play cooperatively with peers (prefers solitary play)</li> <li>Little interest in toys</li> <li>Insists on sameness in routine</li> <li>No idea how to approach new skills or toys</li> <li>Cannot use blocks to build simple structures</li> </ul>
3–4 yr: language	<ul style="list-style-type: none"> <li>Does not engage in back-and-forth communication for purely social reasons</li> <li>Does not talk about what communicative partners are talking about</li> <li>Uses language that is repetitive or recycled from other contexts</li> </ul>

**Table 195-2** Red Flags in Language and Play—cont'd

AGE	WARNING SIGNS AND RED FLAGS
4–5 yr: play	Cannot follow simple rules in play Prefers solitary play Insists on sameness in play Reacts strongly to change Does not engage in symbolic or imaginative play Does not integrate other children in play
4–5 yr: language	Weak ability to hold a conversation Cannot tell a personal narrative Difficulty with sequencing information Uses language that is repetitive or recycled from other contexts

and 30 months or whenever concerns arise in the course of surveillance. In addition, the recommendation for screening for autistic spectrum disorders at 18 and 24 months allows additional insight into the development of communication and social skills. After a systematic review in 2006, the US Preventive Services Task Force concluded that there is no single screening instrument that serves as a gold standard for screening specifically for language disorders, and there were no universally agreed-on recommendations for age or interval for speech and language screening. However, it is generally agreed that use of standardized screening instruments can assist the pediatrician in assessing a young child's general development and making decisions as to whether referral for further evaluation by developmental specialists would be appropriate. Screening instruments vary in format and applicability to particular populations. Table 195-3 provides a partial list of both general and language-specific screening instruments that can be used in the primary care setting. The resource provided by the AAP Developmental Screening task force lists additional tools.

## LANGUAGE DISORDERS

A language disorder as defined by the American Speech and Hearing Association can be classified as any disturbance to an individual's ability to develop and produce spoken or written language. This encompasses both the ability to comprehend and the ability to express language at an age-appropriate level. Language disorders, both developmental and acquired, represent a heterogeneous set of difficulties that range from mild to severe. Children with receptive language deficits have difficulty comprehending language. Of note, a receptive deficit is rarely seen in isolation, and in typical development, comprehension precedes expression of new and more mature language forms. Difficulty with comprehension manifests as reduced understanding of conversation and problems both with following directions and interpreting the intentions of others. Receptive language generally develops in advance of expressive language, except in very rare circumstances (eg, hydrocephalus, severe language processing disorder, and in autism spectrum disorders). Children with expressive language deficits have problems using language to express their most basic wants and needs as well as more sophisticated

thoughts, feelings, and intentions. They may have a hard time putting words into sentences; sentences may be simple and short with confused syntax or verb tense errors, or there may be difficulty finding the right words. A child's vocabulary might be below the level of other children the same age; or the child might use words and phrases repetitively or pick up scripts from videos, commercials, and television. Language impairment might also become apparent as a deficit in stringing sentences together to tell a cohesive story or personal narrative.

A language disorder can be characterized by deficits in the form (comprehension and expression of linguistic rules and syntax), the content (vocabulary and semantics), or the use (discourse pragmatics) of language. Difficulty acquiring and using the rules applicable to the sounds, words, phrases, and sentences or the surface features of what is being said constitutes a deficit in the *form* of language. For children with disorders of *content*, speaking may come easily, but often what they have to say lacks substance. Their discourse is missing the essential ingredients such as objects, events, relations between people, and cultural references that give meaning to the utterance. Pragmatic deficits result in weakness in language *use*, in managing and understanding the why, when, and where aspects of discourse. Children with this difficulty have a hard time selecting and maintaining topics, taking turns in conversation, choosing their style of speech to match the listener or context, using intonation to signal intention, and understanding the non-verbal aspects of language such as proximity, body posture, facial expression, and flexible gaze shifting.

Language-based learning disabilities present as problems with reading, spelling, or writing in addition to the aforementioned oral language deficits. Typically, children with such disabilities have trouble expressing ideas, finding words, learning new vocabulary, comprehending questions, following directions, and retaining written material. They struggle learning the alphabet, spelling rules, multiplication tables, and other rote-memorized information, all of which make it difficult to achieve academically.

## SPEECH DISORDERS

Speech disorders manifest as articulation errors past the age of expectation. *Articulation* is the movement of

the speech mechanism (palate, lips, tongue, jaw, larynx) to create sound. *Phonology* is the rule system that governs how speech sounds interact with one another. A child with a lisp has a problem with articulation; a child who substitutes all K sounds with T (“otay” for okay) has a phonological problem. For pediatricians, knowing when to refer for evaluation is key. As a guideline, a 2-year-old should be 50% intelligible, a 3-year-old 75%, and a 4-year-old fully intelligible to a stranger, not just family and familiar adults.

A child might present with speech problems for several reasons. Some errors are developmental and will resolve in time, and others will need intervention. Some errors are related to the architecture of the mouth, and others are rule-based errors (phonologic). If the errors persist, or the child expresses frustration, an evaluation is in order. When a child makes errors

that are inconsistent, a motor speech disorder should be suspected. Apraxia is a motor speech disorder caused by a difficulty planning and executing speech sounds that cannot be attributed to muscle weakness or paralysis. Key characteristics include limited repertoire of vowels and vowel errors. The error patterns are typically highly variable, with unusual and idiosyncratic error patterns. Errors increase with the length and complexity of utterances, such as in multisyllabic or phonetically challenging words. If apraxia is suspected, a child should be evaluated as soon as possible because the earlier intervention begins, the better the outcome. *Stuttering* or *dysfluency* is a speech disorder characterized by breaks in fluency that can affect sounds, syllables, or words. In young children there can be a period of normal dysfluency between 2 and 4 years of age. The decision to refer for

evaluation should be based on how long dysfluency has persisted, whether there is a family history, the type of repetitions, and secondary behaviors. Indications for evaluation include dysfluency that persists for more than 6 months, family history of stuttering, awareness of difficulty, or anxiety or frustration related to speaking. In addition, if breaks in fluency are partial words, single sounds, silent or accompanied by any secondary or atypical behaviors, or if the balance of dysfluent speech to fluent speech is more than 10% of the overall communication, evaluation should be initiated.

## DIFFERENTIAL DIAGNOSIS

Delays in speech and language milestones are often the first indication of the presence of a developmental disorder. Hearing loss is an important consideration in any child who exhibits delayed acquisition of language milestones or unclear or atypical patterns of speech. Careful history and observation may suggest accompanying delays in other domains indicating more global involvement, as in intellectual disability. Subtle delays in communication can be apparent even before verbal communication is questioned. The phenomenon of joint attention, as evidenced by gaze sharing or pointing, can be documented as early as 8 to 10 months of age. The absence of joint attention should alert the physician to the possibility of an autism spectrum disorder. In the absence of the above conditions, *specific language impairment* (SLI), refers to the developmental disorders affecting primarily receptive, expressive, or mixed receptive-expressive language impairments, whereas *phonologic disorders* refer to conditions affecting the clarity of speech.

## THERAPEUTIC CONSIDERATIONS: WHAT THE PEDIATRICIAN NEEDS TO KNOW

Once a speech and language delay is suspected, referral for diagnostic evaluation is critical to determine the extent of impairment, characterize the nature of the disability, and suggest strategies for intervention. Referral for early intervention evaluation for children from birth to age 3 years, or to the Department of Education for children 3 years and older, offers a means of evaluation within a mandated time frame and services based on the evaluation results. Ideally, this evaluation is conducted by a multidisciplinary team, on which the speech and language pathologist (SLP) plays a key role. The SLP will gather information regarding communication across a variety of contexts. He or she will evaluate the child's ability to comprehend directions, stories, and other communication as well as vocabulary, grammar, and syntax and use of language for a variety of purposes. In certain circumstances, based on the presenting problems, speech sound development, literacy skills, writing, reading comprehension, and fluency will also be evaluated. This assessment should contain informal components such as pretend play in young children and conversation and storytelling in older children. Formal testing with standardized instruments can corroborate and

elucidate informal findings and should always be considered.

The pediatrician should order a formal hearing test to be done by an audiologist. Speech and language therapy should not be delayed pending definitive audiologic evaluation, however, because it may take months for an uncooperative child to have a hearing test completed. A formal hearing test should be ordered as part of the multidisciplinary evaluation, and hearing status should be followed according to recommendations of the audiologist as therapy progresses.

Any child with significant exposure to a second language or dialect is considered bilingually-exposed. Regardless of the type of exposure, simultaneous or sequential, such a child must be evaluated in both languages to determine the presence or absence of language impairment. Many children who are bilingually exposed may go through a short period of language loss, especially if recently exposed to a new language. There may be a delay in mastering some grammatical aspects of both languages, and vocabulary may be judged to be insufficient if words in both languages are not considered. Such children should be assessed by a qualified *bilingual* SLP. If a language impairment is documented in a bilingually exposed child, it is important to determine the dominant language when initiating therapy.

## PROGNOSIS

Based on their presentation and degree of severity, language disorders may resolve with intervention by the time a child enters the early school years. More often, they persist to some degree for the lifetime of the individual. Children identified with speech and language delays in toddler and preschool years are known to be at special risk for behavioral difficulties and for problems with socializing. The association between communication difficulties and externalizing disorders (attention deficit/hyperactivity disorder, oppositional defiant disorder) and internalizing disorders (anxiety disorders, depression) has also been described. The link between early language and later learning problems is also well documented. Children identified with communication impairments at age 4 to 5 years are likely to have significantly more difficulty in reading, writing, and overall academic achievement at ages 7 to 9 years. In addition, these children have more difficulty with peer relationships and less satisfaction with school than their peers.

A multitude of factors determine the outcome of children with speech and language impairments. Important considerations include nonverbal intelligence, type and degree of language disability, and response to intervention. Preschool-aged children with primarily expressive phonologic impairments tend to have a lower risk for later reading problems than those who demonstrate difficulty with phonologic awareness (eg, rhyming, letter-sound association). It is generally agreed that children with language problems that persist until kindergarten entry have a high risk for continuing problems throughout the school years. Parents should be counseled that providing a language-rich environment, stressing verbal interaction and literacy,

is recommended, in addition to specific therapy, to mediate the effects of a language delay (eg, the Reach Out and Read program, [www.reachoutandread.org](http://www.reachoutandread.org)).

## CONCLUSION

Speech and language delays are common and are readily detected in the context of the developmental surveillance and screening that are part of primary pediatric care. These delays may be associated with impairments limited to the domains of speech and language or may signal the presence of conditions such as hearing impairment, intellectual disability, or autistic spectrum disorders. Using the knowledge of risk factors and attention to “red flags” suggesting these disorders is the first step to referral for appropriate evaluation and interventions to minimize associated difficulties with learning, behavior, and socialization.

## Chapter 196 SPLENOmegaly

Marina Reznik, MD, MS; Philip O. Ozuah, MD, PhD

*Splenomegaly* is an enlargement of the spleen resulting from abnormalities of its lymphoid, reticuloendothelial, or vascular components. Although splenomegaly is often considered to be an ominous clinical finding, certain normal variants have been found. In children, as a result of the thinness of the abdominal musculature, a palpable spleen is commonly encountered. Thus a soft spleen is normally palpable in 15% to 30% of neonates. By 1 year of age, 10% of healthy children have a palpable spleen. Even after 10 years of age, 1% of children have a palpable spleen.

Wide interobserver variability exists in the ability to appreciate an enlarged spleen on examination; this variability is not generally associated with clinical experience. The spleen moves downward with inspiration and enlarges diagonally across the midline toward the right iliac fossa.

An enlarged spleen may extend into the pelvis; thus, when examining a child with suspected splenomegaly, the physician should start palpating in the right lower quadrant and move across the abdomen toward the left upper quadrant. As the spleen enlarges, it replaces the tympany of the stomach and colon with the dullness of a solid organ. Percussion cannot confirm splenic enlargement, but it can raise suspicion of it. If tympany is prominent, especially laterally, then splenomegaly is not likely. In addition, a change from tympany to dullness on inspiration when percussing at the lower interspace in the left anterior axillary line suggests splenic enlargement.

Spleen size is conventionally recorded as “centimeters below the costal margin” in the midclavicular and anterior axillary lines. Measuring this span with a rigid ruler gives the most reproducible measurement.

Spleen length is correlated with age, height, weight, and body surface area in a nonlinear fashion, similar to the liver. No sex-based differences in spleen size have been found. Imaging of the spleen with ultrasonography, high-frequency ultrasonography, radioactive (technetium-99m) sulfur colloid scintigraphy, computed tomography (CT), or magnetic resonance imaging (MRI) can be an important adjunct to the physical examination in defining pathologic changes

in this organ. Contrast-enhanced sonography is a novel technique that allows real-time assessment of the spleen.

## DIFFERENTIAL DIAGNOSIS

When assessing a child with splenomegaly, the major splenic functions should be kept in mind: its hematopoietic, phagocytic, and immunologic roles and its role as a reservoir for blood-borne elements. The spleen is a major hematopoietic organ during fetal life. However, it is capable of resuming extramedullary hematopoiesis in children and adults with bone marrow failure. The spleen removes the senescent and abnormal red blood cells, as well as particulate material, from the blood. A major lymphoreticular organ that acts as a filter for infectious organisms in the blood, the spleen also acts as a site of immunoglobulin M and properdin production. Finally, the spleen acts as a reservoir for platelets, reticulocytes, and plasma proteins, especially factor VIII. Because the spleen has so many functions, splenomegaly may be caused by systemic infections, by an increase in normal splenic process (as seen in hemolytic anemia), by infiltration of storage diseases or malignancies, by congestion from splenic or portal vein obstruction, or by inflammatory diseases. The spleen is the organ most commonly injured following blunt abdominal trauma. Engorgement caused by splenic trauma with subcapsular hemorrhage may manifest as an enlarged, tender spleen. The differential diagnosis of splenomegaly is provided in Box 196-1.

## Infections

In infectious processes, splenomegaly results from hypertrophy of lymphatic and reticuloendothelial elements. Viral infections are the most common causes of splenomegaly in children. The splenic enlargement is usually transient and mild to moderate in severity. Infectious mononucleosis from Epstein-Barr virus, cytomegalovirus, and HIV infections leads to a greater degree of splenic enlargement. Specifically, splenomegaly occurs in 50% to 75% of cases of infectious mononucleosis. Subacute bacterial endocarditis, tuberculosis, and other chronic bacterial infections may cause splenic enlargement. Septicemia from meningococcus or pneumococcus may also be associated with splenomegaly. Malaria and visceral leishmaniasis are common causes of splenomegaly in areas endemic for these diseases. Progressive disseminated histoplasmosis can occur in healthy children younger than 2 years who have been exposed to fungus in endemic areas of the eastern and central United States (Mississippi, Ohio, and Missouri River valleys). Early manifestations of this disease include fever, failure to thrive, and hepatosplenomegaly.

## Hematologic Disorders

Splenomegaly associated with hemolytic states, such as membranopathies, hemoglobinopathies, and autoimmune hemolytic anemia, results from engorgement of the splenic sinusoids by abnormal red blood cells, as well as by increased phagocytic activity (work hypertrophy) of the reticuloendothelial elements. Splenic

### BOX 196-1 Differential Diagnosis of Splenomegaly

#### INFECTIONS

- Viral: Epstein-Barr virus, cytomegalovirus, human immunodeficiency virus (HIV)
- Bacterial: acute bacterial infections, subacute bacterial endocarditis, congenital syphilis, tuberculosis
- Parasitic: malaria, toxoplasmosis, leishmaniasis
- Fungal: candidiasis, histoplasmosis, coccidioidomycosis

#### HEMATOLOGIC DISORDERS

##### *Hemolytic Anemias—Congenital and Acquired*

- Red cell membrane defects: hereditary spherocytosis, hereditary elliptocytosis
- Red cell hemoglobin defects: sickle cell disease and related syndromes, thalassemia
- Red cell enzyme defects: glucose-6-phosphate dehydrogenase deficiency, pyruvate kinase deficiency, etc
- Autoimmune hemolytic anemia

##### *Extramedullary Hematopoiesis*

- Thalassemia major, osteopetrosis, myelofibrosis

#### INFILTRATIVE DISORDERS

- Leukemias
- Lymphomas

- Lipidoses
- Mucopolysaccharidosis
- Langerhans cell histiocytosis

#### CONGESTIVE SPLENOMEGALY

- Portal vein thrombosis
- Hepatic cirrhosis
- Congestive heart failure
- Hepatic portal or splenic vein obstruction

#### INFLAMMATORY DISEASES

- Systemic lupus erythematosus (SLE)
- Juvenile idiopathic arthritis (JIA)
- Serum sickness
- Sarcoidosis
- Immune thrombocytopenias and neutropenias

#### PRIMARY SPLENIC DISORDERS

- Splenoptosis (wandering spleen)
- Cysts
- Hemangiomas and lymphangiomas
- Subcapsular hemorrhage
- Accessory spleen

enlargement as a result of extramedullary hematopoiesis occurs in diseases associated with increased demand on the bone marrow for cell production (thalassemia major). Measurement of the spleen's size and recording the result are an essential part of every physical examination in children with sickle cell disease. It is important to have this baseline information because a rapidly enlarging spleen with a falling hematocrit, pallor, dyspnea, weakness, and left-sided abdominal pain suggests the diagnosis of acute splenic sequestration crisis—a leading cause of death in children with sickle cell anemia and a medical emergency that requires prompt recognition and treatment.

### **Infiltrative Disorders**

The spleen is commonly enlarged in untreated leukemias and lymphomas, including Hodgkin disease. Malignant infiltration of the spleen often produces a massively enlarged, firm spleen that crosses the midline of the body. In the lipidoses and mucopolysaccharidoses, the phagocytic reticuloendothelial elements of the spleen accumulate large amounts of lipid and mucopolysaccharide, respectively. In Langerhans cell histiocytosis, the spleen is infiltrated by histiocytes.

### **Congestive Splenomegaly (Banti Syndrome)**

Splenomegaly may occur from obstruction of the hepatic, portal, or splenic veins. The most common causes include portal vein thrombosis, hepatic cirrhosis, and congestive heart failure. Umbilical vein catheterization or septic omphalitis in neonates may also result in obliteration of these vessels. Congestive splenomegaly is the most common cause of hypersplenism (the term used to describe patients with splenomegaly, peripheral blood cytopenias from excessive splenic function, and increased bone marrow production of the affected blood cells).

### **Inflammatory Diseases**

Splenomegaly seen in inflammatory diseases such as systemic lupus erythematosus (SLE), juvenile idiopathic arthritis (JIA), sarcoidosis, and serum sickness is the result of increased numbers of reticuloendothelial cells that remove antibody-coated cells and proteins. Lymphoid hyperplasia may occur as a result of accelerated antibody production in the spleen.

### **Primary Splenic Disorders**

Splenoptosis, or wandering spleen, is a congenital fusion anomaly of dorsal mesogastrium that results in a spleen of normal size that moves freely within the peritoneal cavity. A patient with splenoptosis usually has an asymptomatic abdominal mass. Splenic cysts may mimic splenomegaly. Two types of splenic cysts have been identified: those that are congenital (epidermoid) and those that are acquired (pseudocyst) from trauma or infarction. Cysts are generally asymptomatic and are confirmed by radiologic studies. Abdominal trauma may cause subcapsular hemorrhage of the spleen that results in abdominal pain and splenomegaly. Accessory spleens, which are found in 15% of individuals, may also mimic splenomegaly.

## **EVALUATION**

### **History**

The cause of splenomegaly can be determined by history and physical examination in addition to laboratory tests and, if necessary, radiographic studies. A thorough history, including travel and family history, may provide valuable clues to the possible cause of splenomegaly. In a child with a history of a fever, pharyngitis, malaise, and splenomegaly, a viral cause (Epstein-Barr virus, cytomegalovirus) should be considered. Malaria or histoplasmosis may be the cause if the patient has recently traveled to areas endemic for these diseases. In the patient with fever, night sweats, malaise, weight loss, rash, arthralgia, and bone pain, an underlying inflammatory, infectious, or malignant process should be suspected. A newborn with unexplained jaundice and a family history of anemia, jaundice, splenomegaly, or splenectomy most likely has a congenital hemolytic anemia. A history of umbilical vein catheterization or omphalitis in the neonatal period may suggest a diagnosis of portal vein thrombosis.

### **Physical Examination**

The normal palpable spleen is soft, smooth, and nontender and is less than 1 to 2 cm below the left costal margin. A pathologically enlarged spleen is usually firm, has an abnormal surface, and is often associated with signs and symptoms of an underlying disease. An enlarged spleen may be tender if it has enlarged quickly (splenic sequestration, splenic trauma with subcapsular hemorrhage). When portal hypertension causes splenomegaly, dilation of the superficial abdominal veins can be noted at physical examination. Findings of a rash, arthritis, mucosal ulcerations, and splenomegaly may suggest an autoimmune disorder. Although a palpable spleen may be a normal variant, the concomitant finding of hepatomegaly is usually pathologic and should prompt further investigation.

### **Laboratory Evaluation**

The initial laboratory testing of a child with splenomegaly should include a complete blood count with a white blood cell differential, reticulocyte count, and examination of the peripheral blood smear. Further laboratory investigations should be directed at the suspected diagnosis, as indicated by the history, physical examination, and the results of the initial laboratory tests.

### **Imaging Studies**

Radiologic confirmation of a mass in the left upper quadrant should be performed if any question exists about the nature of the mass. Retroperitoneal tumors such as neuroblastoma and Wilms tumor may be mistaken for an enlarged spleen. Ultrasonography is used to quantify splenic enlargement and to differentiate the spleen from other left-upper-quadrant abdominal masses. CT scanning has been used to evaluate splenic trauma and focal splenic pathology. Contrast-enhanced ultrasonography is a novel technique used to detect bleeding sites and hematomas in splenic

trauma. MRI of the spleen can further clarify abnormalities in size and shape and can define parenchymal disease. Technetium-99m sulfur colloid scan is used to assess splenic function.

## TREATMENT

Treatment of splenomegaly should be aimed at the underlying disease entity. Patients who have bacterial infections should receive appropriate antimicrobial therapy. Viral causes of splenomegaly generally respond to supportive care. With splenomegaly from infectious mononucleosis, patients should refrain from contact or collision sports until the illness has completely resolved clinically and the spleen has returned to a normal size, generally at least 4 weeks from the onset of illness. Some experts suggest a sonographic evaluation of spleen size to help decide when the patient can resume full athletic activity.

Splenectomy may be indicated to help control or stage some diseases that cause splenomegaly. Such diseases include hereditary spherocytosis, autoimmune thrombocytopenia or hemolysis, and lymphoma (Hodgkin lymphoma). Splenectomy may also be indicated for the treatment of chronic, severe hypersplenism. Laparoscopic splenectomy is being performed more commonly in children and has been found to be a safe procedure, with a shorter hospital stay, compared with open splenectomy. During the past decade, partial splenectomy has become a viable therapeutic alternative to total splenectomy. Removal of up to 90% of the enlarged spleen usually provides relief from splenomegaly while retaining sufficient splenic tissue for immune competence. Partial splenectomy has been used successfully in children with hereditary spherocytosis, nonparasitic splenic cysts, sickle cell disease, and thalassemia. All children without spleens are at risk for fulminant bacteremia, sometimes referred to as overwhelming postsplenectomy infection (OPSI), particularly from *Streptococcus pneumoniae*, *Haemophilus influenzae* type b, and *Neisseria meningitidis*, and should receive needed immunizations at least 2 weeks before surgery if possible. Twice-daily penicillin prophylaxis against pneumococcal infections (in addition to immunization) is recommended for these children if they are younger than 5 years and for at least 1 year after splenectomy. Some experts continue prophylaxis throughout childhood and into adulthood for particularly high-risk patients with asplenia.

### WHEN TO REFER

- Splenomegaly with concomitant adenopathy or hepatomegaly
- Palpation of a hard spleen
- Suspicion of malignancy or other infiltrative disorders
- Evidence of hemolytic anemias

### WHEN TO ADMIT

- Splenic sequestration in sickle cell disease
- Injury to the spleen from abdominal trauma

## Chapter 197 STRIDOR

Alfin G. Vicencio, MD; John P. Bent, MD

## DEFINITION

Stridor is typically a high-pitched, monophonic noise caused by turbulent airflow through a partially obstructed extrathoracic airway, heard predominantly on inspiration. Although obstruction of large intrathoracic airways (ie, main-stem bronchi, mid and distal trachea) can produce a similar noise on expiration, these lesions are more thoroughly covered in Chapter 208, Wheezing, and will not be discussed here.

During the normal respiratory cycle, rhythmic expansion and contraction of the thorax leads to dynamic changes in thoracic pressures, allowing air to flow into and out of the lungs. (For a schematic representation, see Figure 208-1, Chapter 208, Wheezing.) During expiration the volume of the thoracic cavity decreases, creating positive pressures within the thorax. Airways located within the thorax are directly subjected to these positive pressures and thus are more prone to obstruction during expiration, leading to turbulent airflow and wheezing. On inspiration the thoracic cavity expands, resulting in negative intrathoracic pressures and improved patency of intrathoracic airways. However, because the intraluminal airway pressure drops to allow inflow of air, and because the extrathoracic airways (nose, nasopharynx, oropharynx, and larynx) may collapse from transmitted negative intrathoracic pressures, this portion of the airway is susceptible to obstruction, and thus stridor, during inspiration.

Because the extrathoracic airways extend from the nose to the proximal trachea, high-pitched laryngeal stridor must be differentiated from other abnormal inspiratory noises, such as stertor, a noisy, rumbling-type noise similar to snoring, which can be heard with partial airway obstruction in the oropharynx or nasopharynx. Accurately recognizing stridor will facilitate the ensuing diagnostic tests, given that the offending

lesion is likely to be in or around the glottic region, a relatively focused anatomic area.

## DIFFERENTIAL DIAGNOSIS

Because stridor reflects obstruction of a large centralized airway and can range in severity from mild to life-threatening, ensuring airway patency should precede the generation of a differential diagnosis. For the child who has signs of severe respiratory compromise—distressed appearance, severe retractions, nasal flaring, pallor or cyanosis, altered mental status—initial measures should focus on maintaining the airway and, if possible, relieving the obstruction. Only personnel skilled at airway management should attempt intubation, if required, and such a procedure should be performed in as controlled a setting as possible. In select situations for which medical intubation might prove difficult (ie, suspected epiglottitis in a patient with high fever, drooling, and severe respiratory distress), surgical support should be present before airway manipulation in the event that tracheostomy is required. Luckily, most cases of stridor that the general pediatrician encounters can be approached with a succinct, focused history and physical examination followed by directed diagnostic tests.

The most common causes of stridor in the pediatric age group, laryngomalacia and viral croup, can be easily recognized by the experienced physician after obtaining a focused history and physical examination (see Evaluation). However, because the differential diagnosis of stridor is extensive and includes anything that obstructs the extrathoracic airway, a major challenge for the pediatrician is identifying select patients who have less common causes of obstruction and thus require specific diagnostic tests and different management (Table 197-1). For example, laryngomalacia, vocal cord dysfunction, subglottic stenosis, laryngeal papillomatosis, glottic cysts, laryngeal webs, subglottic hemangiomas, foreign bodies, retropharyngeal abscesses, and laryngeal fractures can all compromise the extrathoracic airway and cause stridor. In most cases a careful stepwise evaluation by the astute pediatrician will lead to the correct diagnosis.

## EVALUATION

### History

Once airway patency has been ensured, a focused history should be elicited. Age of initial presentation and a description of the events surrounding the onset of symptoms can provide important clues to the underlying

**Table 197-1** Causes of Stridor

	HISTORY	OBJECTIVE FINDINGS
Laryngomalacia	<ul style="list-style-type: none"> <li>• Develops in the first few months of life</li> <li>• Present mostly when agitated or crying</li> </ul>	<ul style="list-style-type: none"> <li>• Predominantly inspiratory</li> <li>• May be positional</li> <li>• Obstruction of glottic space by collapsing supraglottic structures on laryngoscopy</li> </ul>
Viral croup	<ul style="list-style-type: none"> <li>• Preceded by upper respiratory tract infection symptoms and fever</li> <li>• No stridor between episodes</li> <li>• May have history of similar episodes in past</li> </ul>	<ul style="list-style-type: none"> <li>• Predominantly inspiratory</li> <li>• No change with position</li> </ul>

diagnosis. A commonly encountered patient is one whose stridor is preceded by fever, upper respiratory symptoms, and a *barky* or *seal-like* cough. This history, which may include repeated and similar episodes in the past, is consistent with viral croup and is easily recognized by an experienced pediatrician. Stridor beginning in the first few weeks of life that is present only during specific phases of alertness such as eating, sleeping, or excitement suggests congenital laryngomalacia as the underlying cause. Indeed, laryngomalacia is the most common cause of congenital stridor in infancy. In comparison, continuous stridor that begins soon after birth might suggest a congenital and fixed lesion such as a laryngeal web or, particularly in an infant with cutaneous hemangioma, subglottic hemangioma (obstruction associated with subglottic hemangiomas typically is mild at birth and worsens over the first 6 months of life).

Stridor that develops shortly after a prolonged intubation likely results from subglottic stenosis or granulation tissue and is often seen in premature infants who required mechanical ventilation during the neonatal period. A less common but important patient to recognize is one with a history of Arnold-Chiari malformation or hydrocephalus. Because increasing intracranial pressure can result in bilateral vocal cord paralysis, such patients should receive appropriate and emergent care to prevent brainstem herniation. Similarly, a stridulous toddler with a history of choking or placing small objects in the mouth should be evaluated for the presence of a foreign body. Recurrent respiratory papillomatosis is also usually associated with stridor or hoarseness 2 to 3 years after birth, although the infection is acquired through vertical transmission in the birth canal from maternal cervical human papillomavirus infection.

In addition to their onset, the chronicity and progression of symptoms can help identify the underlying cause and can be particularly helpful for patients with presumed laryngomalacia or viral croup who do not follow the expected clinical course. Stridor caused by laryngomalacia is typically intermittent and worsens over the first several months of life. As the child becomes older, such episodes become less severe and less frequent. Indeed, for most patients with laryngomalacia, symptoms will completely resolve by the first birthday. Similarly, the likelihood of developing stridor caused by viral croup lessens with age. When the pediatrician is faced with a child whose stridor worsens or persists rather than improves, coexisting or alternate diagnoses should be considered, and appropriate diagnostic testing should be initiated. In addition, persistent symptoms may indicate a different laryngeal abnormality. For example, mild stridor caused by a subglottic hemangioma may initially be attributed to a more common problem such as laryngomalacia. Similar to laryngomalacia, obstruction from a hemangioma tends to worsen after initial presentation as the lesion enlarges. Unlike laryngomalacia, natural resolution of the hemangioma, and thus the stridor, may take several years rather than months. History of a hoarse voice or cry suggests glottic disease and might result from chronic irritation of the vocal cords. Other clues that suggest more ominous conditions include constant stridor, failure to thrive, difficulty swallowing, and severe and sudden onset of symptoms. Last, onset of stridor in an older child or

adolescent with no previous history should prompt a more thorough evaluation.

### Physical Examination

Laryngeal stridor represents airway obstruction at the level of the supraglottis, glottis, or subglottis. Although these anatomic regions can be difficult to examine without the use of specific diagnostic tests, several clues from thorough physical examination can help confirm suspicions elicited on history. General inspection of the patient should include an assessment of position—extension of the neck is often described in patients with a serious infection such as epiglottitis or retropharyngeal abscess—as well as any drooling, which might suggest mass effect or edema in the posterior pharynx causing dysphagia in addition to the stridor (of note, these patients often exhibit stertor rather than stridor). Because such entities can be difficult or even dangerous to visualize, attention should focus on keeping the patient calm and maintaining the airway. An oropharyngeal examination might reveal a retropharyngeal bulge, an enlarged epiglottis or a lateral displacement of the uvula, and swelling of a tonsillar pillar from an underlying infection in patients with acute onset of stridor. External examination of the neck might show suprasternal retractions when obstruction is severe and may also reveal displacement of the larynx, a mass obstructing the airway, or signs of trauma. Finally, the quality of the voice should be noted; given that hoarseness, aphonia, or a weak cry suggests vocal cord disease, one should examine the skin for any cutaneous lesions such as hemangiomas. Lastly, improvement of stridor with a jaw thrust could suggest pathology in the region of the epiglottis as opposed to the subglottis.

### Objective Testing

Although a detailed history and physical examination are often sufficient to make a diagnosis of laryngomalacia or viral croup, additional diagnostic tests are warranted for patients whose symptoms and clinical course seem unusual or overly severe. Laboratory testing has limited value in evaluating patients with stridor. Similarly, pulmonary function testing is not often necessary but can confirm suspicions of an extrathoracic obstruction (Figure 197-1). A simple radio-

**Figure 197-1** Findings on spirometry. The normal flow-volume loop has a characteristic shape. In comparison, the flow-volume loop in a patient with severe subglottic stenosis is flat.

**Figure 197-2** The neck radiograph demonstrates a mass causing mild obstruction of the subglottic area (arrow) in a child with stridor.

**Figure 197-3** Normal larynx. Flexible and direct laryngoscopy offers a direct view of the glottis and can identify an abnormality. Shown here is a normal view of the glottis.

**Figure 197-4** Flexible laryngoscopy. A, Topical anesthetic is applied before performing flexible laryngoscopy. B, The procedure is usually well tolerated when performed by an experienced laryngoscopist.

graph of the neck can identify obstructive lesions in the retropharynx, glottis, and subglottic area (Figure 197-2). The classic *steep sign* on anteroposterior neck radiograph depicts subglottic narrowing but does not distinguish croup from subglottic stenosis. Direct visualization of the airway by flexible laryngoscopy often provides definitive information.

Flexible laryngoscopy is a routine procedure for the practicing otolaryngologist. Because the procedure offers direct visualization of the posterior pharynx and glottis (Figure 197-3), numerous other lesions causing laryngeal obstruction can be visualized, leading to a correct diagnosis. In fact, before routine use of office-based flexible laryngoscopy, laryngomalacia was known as *congenital laryngeal stridor*, reflecting physicians' incorrect assumption that all congenital laryngeal stridor might be attributed to a single cause. The procedure is usually well tolerated and can be performed most often with topical anesthesia alone (Figure 197-4). In many instances, laryngoscopy merely confirms the presence of laryngomalacia while excluding other causes of airway obstruction.

**Figure 197-5** Laryngomalacia as seen by flexible laryngoscopy. **A**, During expiration the glottis is patent, and no abnormal sound is heard. **B**, During inspiration the epiglottis and arytenoids collapse and compromise the glottic opening, causing inspiratory stridor. **C**, In cases of severe laryngomalacia, surgical resection of redundant tissue can improve the glottic patency even during inspiration.

**Figure 197-6** Obstructive lesions in the glottis. **A**, Laryngeal papilloma. **B**, Anterior saccular cyst. **C**, Glottic web.

**Figure 197-7** Obstructive lesions in the subglottic region. **A**, Severe subglottic stenosis. **B**, Right lateral subglottic hemangioma. **C**, Subglottic duct cyst.

(Figure 197-5, A and Figure 197-5, B). In cases of severe laryngomalacia, laryngoscopy can also identify specific structures of the larynx that are causing obstruction that might be amenable to surgical correction (Figure 197-5, C). Of course, direct visualization of the glottis can also identify other lesions that cause obstruction, as shown in Figure 197-6.

Successful flexible laryngoscopy is often dependent on patient cooperation, particularly with anxious, difficult-to-restrain, and younger school-aged children. Furthermore, although laryngoscopy often provides a clear view of the glottis and supraglottic structures, the subglottic area cannot be well visualized. Indeed, even with a cooperative patient, the presence of severe

laryngomalacia might obscure the view of the subglottic area such that a more distal lesion would not be visible. In such cases, direct visualization of the subglottic region and proximal trachea may be indicated to exclude a second lesion. Direct laryngoscopy and bronchoscopy under sedation or general anesthesia can help diagnose and quantify the severity of subglottic stenosis or identify other subglottic lesions that cause obstruction (Figure 197-7).

## MANAGEMENT

Because patients with laryngomalacia and viral croup are frequently encountered and will include most patients with stridor, the general pediatrician should

be comfortable with outpatient management. Most cases of laryngomalacia can be managed with observation alone, with particular attention given to adequate caloric intake and weight gain. For patients with severe episodes of stridor causing hypoxemia or cyanosis, or if symptoms progress over time, additional diagnostic testing is indicated, and referral to a subspecialist may be warranted. In certain instances, laryngomalacia requires surgical management to relieve the obstruction caused by redundant epiglottic folds or arytenoid tissue (see Figure 197-5). Tracheostomy is rarely required. As with laryngomalacia, most patients with viral croup can be managed with close observation alone. For children with more severe obstruction (nasal flaring, retractions), racemic epinephrine and dexamethasone may temporarily relieve symptoms of obstruction and alleviate inflammation, respectively. Hospitalization is indicated for children with hypoxemia, apnea, or poor feeding or dehydration.

As discussed previously, stridor that is continuous, progressive, or severe should prompt the pediatrician to initiate additional diagnostic tests. Referral to a pediatric otolaryngologist for further evaluation by laryngoscopy or bronchoscopy (or both) will facilitate diagnosis of other causes of glottic or subglottic obstruction, which might require surgical management. Laser therapy for a hemangioma or web can provide definitive cure, as can cricoid split and augmentation of the subglottic space for an acquired stenosis.

In summary, the pediatrician evaluating the child with stridor should be aware of the various clinical entities that can present with stridor, be able to recognize by history or physical examination patients who require further evaluation, initiate simple diagnostic tests, and refer to appropriate subspecialty physicians those children with unusual presentations or poor response to conventional therapies.

### WHEN TO REFER

- Progressive or continuous stridor
- Poor weight gain or growth associated with persistent stridor
- Repeated hospitalization
- Presence of cutaneous hemangiomas in association with persistent stridor

### WHEN TO ADMIT

- Respiratory distress or hypoxemia
- Inability to eat or drink
- Altered mental status or signs of fatigue
- Stridor associated with signs of increased intracranial pressure

## Chapter 198

# SUBSTANCE USE: INITIAL APPROACH IN PRIMARY CARE

Sharon Levy, MD, MPH; Sarah Bagley, MD

## INTRODUCTION

Pediatricians in primary care encounter many youth who have experience with alcohol, marijuana, and other drugs. They may identify a youth because parents or teachers have expressed a concern about use of substances, because the youth has physical signs or symptoms suggesting substance use, because there are nonspecific symptoms that may suggest substance use (eg, declining school performance or attendance, car crash, association with friends who are using substances), or because an asymptomatic youth has a positive substance-use screening test result. Whether the use identified is sporadic or regular, it can have negative health effects related to the direct consequences of the substances or associated risky behaviors. Identifying and addressing substance use to minimize harm is an important task for the primary care physician (PCP). Because substance use is closely associated with morbidity and mortality in this age group, the American Academy of Pediatrics (AAP) recommends that pediatricians achieve competence in identifying and intervening to reduce substance use by youth, as well as supporting the care of youth with substance use disorders (SUDs).

Perceived limitations of time for adequate psychosocial evaluation, discomfort addressing sensitive issues, or lack of familiarity with available therapeutic resources may prevent physicians from thoroughly and appropriately addressing substance use with adolescents. However, as with other disorders, assessment is required in order to determine the appropriate setting and level of care. More often than not, sensitivity to these issues, attention to adolescents' risk behaviors in general, and periodic follow-up in the primary care setting are adequate to help keep adolescents safe and healthy.

## ADOLESCENT BRAIN DEVELOPMENT

The human brain continues to develop until the middle of the third decade of life. The prefrontal cortex—which controls impulses, attention and organization—matures last, well after the parts of the brain that are involved in pleasure and reward. This developmental “imbalance” is correlated with stimulation seeking and risk-taking behavior that is typical of adolescence. Use of psychoactive substances is one way, albeit dangerous and unhealthy, in which youth may fulfill a natural inclination for stimulation and reward. It is not surprising, therefore, that rates of psychoactive substance use peak in adolescence and early adulthood. Seen in this perspective, substance use can be understood as an (unhealthy) mechanism for fulfilling a normal drive, rather than as purely deviant behavior. Adolescents also may use psychoactive substances for a variety of other reasons: to fit in social situations in which others are using substances; because of expectations that use will be pleasurable; as a form of risk taking or stimulation seeking; or to relax, relieve anxiety, improve mood, or relieve symptoms of a mental health disorder. Identifying the reasons that underlie substance use can help physicians to target counseling, advice, and strategies that are most salient to the adolescent.

Unfortunately substance use, even without symptoms that rise to the level of a “disorder,” is associated with significant health problems, including injuries, accidents, unintentional sexual activity, and sexually transmitted infections. Early initiation of substance use is also associated with increased risk of developing a severe SUD (otherwise known as addiction), which is a chronic medical condition that causes neurologic changes. The AAP recommends that physicians routinely screen every adolescent for substance use and deliver an appropriate intervention geared towards preventing or reducing substance use. When a child is referred for specialty care of a substance abuse problem, the AAP recommends that the physician remain involved with the child and family, supporting their positive view of treatment, monitoring progress, and providing complementary primary care services.

## PREVALENCE OF SUBSTANCE USE

Alcohol, marijuana, and tobacco are the most commonly used substances among youth. By the end of 12th grade, 52% of students report being drunk at least once, as do 12% of eighth-graders. Lifetime rates of use of any illicit drug increased in 2013, driven mainly by increasing rates of marijuana use. Perception of risk related to marijuana use continues to fall, likely foreshadowing continued increases in use over the next few years. Prescription drug misuse continues to be a concern, with 15% of 12th-graders reporting misuse of a prescription drug in the prior year. Rates of tobacco use by youth declined from 1996 to 2010, though over the past few years rates have plateaued. “E-cigarettes,” which are electronic devices that vaporize liquid nicotine, are marketed as a tobacco cessation device but are sold in flavors such as bubble gum and cotton candy that are attractive to children

who may initiate their “smoking careers” with these devices. Use of tobacco products often precedes use of other substances. Youth who smoke cigarettes are 5 times more likely than nonsmokers to use alcohol, 13 times more likely to use marijuana, and 7 times more likely to use cocaine or heroin.

## CLASSIFICATION OF SUBSTANCE USE DISORDERS

The *Diagnostic and Statistical Manual, 5th Edition (DSM-5)*, released in May 2013, included new criteria and replaced the terms “substance abuse” and “substance dependence” with SUD—mild, moderate, or severe. The new diagnostic classification is based on the number of criteria that are met: 2 to 3 constitute a mild disorder, 4 to 5 moderate, and 6 or more severe. Meeting criteria for a mild or moderate SUD indicates particularly hazardous use or that an individual has begun to have problems associated with use. Although there are no clear referral guidelines for adolescents with an SUD unless there is a co-occurring mental illness, those with a mild SUD can likely be managed in primary care. Patients with a moderate SUD may not require a referral to subspecialty care, and the referral decision can be left to the discretion of the PCP and his or her comfort with managing SUDs. Meeting criteria for severe SUD suggests that an individual would likely benefit from specialized treatment for SUDs. However, because many adolescents with a severe SUD will not accept a referral to treatment, PCPs should be prepared to manage these patients in primary care while trying to facilitate completion of the referral. While not an official diagnostic term, “addiction” refers to loss of control or obsessive use of a substance associated with neurologic changes in the brain’s reward center. Because there is no cure for addiction, long-term treatment is recommended. Effective, evidence-based treatments, including medication and psychosocial support, are available.

The following sections will describe the physician’s role in screening for substance use, assessment of severity, and management of adolescents who are using substances.

## CONFIDENTIALITY AND SUBSTANCE USE

Given that substance use is one of a number of sensitive topics that may come up in the course of adolescent care, PCPs should have a systematic way to establish “limits” of confidentiality with both youth and parents in the practice. This is particularly important before a pediatrician begins taking the medical history and screening for drug use. Discussions between the pediatrician and patient should remain confidential unless the pediatrician determines that the reported behaviors are putting either the patient or someone else at acute risk of harm. Determining whether a behavior requires breach of confidentiality is a matter of clinical judgment; in most cases reports of occasional tobacco, alcohol, or marijuana use can be kept confidential, though a physician may decide to involve parents if a child is very young or being

treated for a medical condition that could be dangerously affected by substance use. Even when there is no reason to breach confidentiality, it is often best to request permission from the youth to engage with parents for their support. In situations where a parent is already aware of use, the youth may be willing to share information, particularly if he or she has agreed to a quit attempt or to engage in further treatment.

## SCREENING TOOLS

At each health supervision visit with an adolescent or preadolescent patient, pediatricians should include a psychosocial interview to assess family and peer relationships, academic progress, recreational activities, sexual behavior, and drug use. HEADSSS is an acronym that can help physicians to inquire about key domains: home, education, activities, drugs, safety, sexuality, and suicide or depression. Pre-visit questionnaires are also available to capture this information.

This data gathering does not substitute for screening. Standardized, validated tools are recommended when screening for substance use in order to improve sensitivity of report and accuracy of triage based on screen results (Table 198-1). Using screening tools minimizes the likelihood that substance use problems or disorders are missed, as commonly occurs when screening on clinical impressions alone.

Screening allows pediatricians to stratify youth into risk categories. Each of the recommended tools does this in a slightly different way, though most include “no use,” “lower-risk use,” “moderate-risk use,” and “high-risk use,” with “lower-risk use” corresponding to use without a *DSM-5* SUD and “high-risk” corresponding to a mild, moderate, or severe SUD. In this chapter we describe interventions for each of these levels of risk. Some tools do not discriminate between moderate and high risk; in these cases the assessment is used to determine which youth have developed a

severe SUD that will benefit most from referral to subspecialty care. Interventions for each stage are described below, in the section on Counseling to Reduce Drug Use and High-Risk Behaviors.

## ADVICE AND COUNSELING FOR LOW-RISK YOUTH

PCPs should provide youth who are not using substances or are “lower risk” with positive encouragement about their smart and healthy choices. This is an opportunity to provide education about the risks of using substances in addition to anticipatory guidance about how to manage situations when alcohol or other drugs will be available. Importantly, it is recommended that the PCP include a discussion of the risks of impaired driving and help the adolescent plan for times when a driver may have used alcohol or drugs. Students Against Destructive Decisions (SADD) has a helpful framework for physicians to use with patients and parents for driving safety (see Tools for Practice: Engaging Patient and Family at the end of this chapter).

## PRIMARY CARE OF YOUTH WHO ARE USING SUBSTANCES

### Assessment

Assessment is performed with youth whose screen result puts them in the “moderate risk” or “high risk” category in order to determine the problems associated with use and the effect of substance use on their functioning at home, at school, and with peers. Assessment can include questions about age of initiation, frequency, and, for alcohol, quantity of use—information that assists the physician in identifying acute risk (such as very heavy alcohol consumption) as well as personalizing medical advice (such as discussing the effect of daily marijuana use on the adolescent brain). Asking about associated problems, troubles, regrets, and quit attempts may also identify areas of ambivalence that

**Table 198-1** Substance Abuse Screening and Assessment Tools for Use With Adolescents

### BRIEF SCREENS

S2BI

- 2-question frequency screen
- Screens for tobacco, alcohol, marijuana, and other illicit drug use
- Discriminates between no use, no SUD, moderate SUD, and severe SUD, based on *DSM-5* diagnoses
- Identifies problematic tobacco, alcohol, and marijuana use in pediatric settings
- 2-question screen
- Screens for friends’ use and own use

Brief Screener for Tobacco, Alcohol, and Other Drugs (BSTAD)  
NIAAA Youth Alcohol Screen

### BRIEF ASSESSMENTS

Car, Relax, Alone, Friends/Family, Forget, Trouble (CRAFTT)

- A good tool for quickly identifying problems associated with substance use
- Not a diagnostic tool
- Assesses for both SUDs and mental health disorders
- Assesses risky drinking
- Not a diagnostic tool

Global Appraisal of Individual Needs (GAIN)  
Alcohol Use Disorders Identification Test (AUDIT)

can be incorporated into a discussion of behavior change. These problems can be used as a fulcrum to turn the discussion toward a behavior change plan identified by the youth.

In general, open-ended questions such as “Tell me about your history of alcohol use” encourage more reporting than closed-ended questions. However, physicians may need to prompt adolescents for certain

information that is important for formulation. Suggested historical elements are listed in Table 198-2. With a focus on problems associated with substance use, a clinical history can be used as the first step in an intervention. Information about use of tobacco, inhalants, and other psychoactive and illicit substances and misuse of prescription or over-the-counter medications also helps to formulate clinical impressions and treatment recommendations. The National Institute of Alcohol Abuse and Alcoholism’s *Alcohol Screening and Brief Intervention for Youth: A Practitioner’s Guide* and the AAP Policy Statement on Screening, Brief Intervention, and Referral to Treatment both explain in detail the recommended approach to screening and brief intervention for adolescents.

A parent, teacher, or other caregiver may notice non-specific signs or symptoms that may indicate substance use. If these are reported, the youth should be assessed for a potential SUD through a careful history regardless of screen results. See Table 198-3 for other conditions that may mimic or co-occur with substance use. In addition, certain risk factors such as early initiation of use, family history of SUDs, and co-occurring mental health disorders increase a youth’s susceptibility to developing an SUD. When available, this information should be considered in the overall assessment of each patient.

As with screening, an accurate substance use history can be best obtained in an atmosphere of confidentiality, privacy, and trust; it is recommended that parents be excluded from the interview.

**Table 198-2** Key Details to Assess in High-Risk Patients

SUBSTANCE	KEY HISTORICAL ELEMENTS
Alcohol	<ul style="list-style-type: none"> <li>• Age of first drunkenness</li> <li>• Frequency of drinking episodes</li> <li>• Typical amount of alcohol consumed</li> <li>• Greatest amount of alcohol consumed</li> <li>• History of blackouts, overdose, emergency department visits</li> <li>• Problems associated with alcohol use</li> </ul>
Marijuana	<ul style="list-style-type: none"> <li>• Quit attempts</li> <li>• Age at initiation</li> <li>• Frequency of marijuana use</li> <li>• History of paranoia and/or hallucinations</li> <li>• Problems associated with marijuana use</li> <li>• Quit attempts</li> </ul>

**Table 198-3** Conditions That May Mimic or Co-occur With Substance Use

CONDITION	RATIONALE
Learning problems or disabilities	Unidentified learning difficulties can contribute to frustration and stress, school failure, and association with peers who use substances, all of which can increase the chances of developing a substance use disorder (SUD). See Chapter 172, Learning Difficulty, to explore this possibility.
Depression or bipolar disorder	Marked sleep disturbance, disturbed appetite, low mood, or tearfulness could indicate that a youth is depressed. Symptoms of depression rapidly alternating with cycles of agitation may suggest bipolar mood disorder. See Chapter 137, Depression.
Exposure to adverse childhood experiences (ACE)	Youth who have experienced or witnessed trauma, violence, a natural disaster, separation from a parent, parental divorce or separation, parental substance use, neglect, or physical, emotional, or sexual abuse are at high risk for developing emotional difficulties such as adjustment disorder or posttraumatic stress disorder (PTSD). Consider PTSD if the onset or acceleration of substance use was preceded by an extremely distressing experience. Physicians should speak separately and confidentially with the youth and parents to explore this possibility. Parents are often unaware of exposures that children may have had at school or in the community and may also underestimate the effect on children of major traumas in the family (eg, serious illness in a parent, maltreatment of the child, death or incarceration of a loved one). See also Chapter 129, Anxiety.
Other anxiety disorders	Anxiety disorders commonly co-occur with SUDs, and the relationship is bidirectional: anxious youth may be more likely to use substances, and conversely, substance use may cause or precipitate anxiety disorders.
Physical illness	Drug or alcohol withdrawal may present as a physical illness and is potentially a medical emergency. Psychiatric symptoms may be associated with medical illness (eg, encephalitis/cerebritis) and may be mistaken for drug intoxication.
Psychosis	Though rare, the onset of bipolar disorder or schizophrenia in late adolescence may be subtle and marked only by frightening hallucinations or delusions that the youth does not disclose. These symptoms may result from, precipitate, or accelerate the use of substances.
Attention-deficit/hyperactivity disorder (ADHD)	Adolescents with ADHD have higher rates of SUDs than peers. Some studies have suggested that stimulant treatment for adolescents with ADHD may lower the risk of developing an SUD, though findings have been inconclusive. There is no evidence that stimulant treatment increases risk of developing an SUD. See Chapter 168, Inattention and Impulsivity.

### Physical Examination

The medical complications of chronic substance use, although sometimes severe, usually do not appear until after adolescence. Nonetheless, a complete evaluation for an SUD includes a complete physical examination; signs and symptoms of acute intoxication or chronic use should be noted if present. Table 198-4 lists physical signs and symptoms of acute and chronic substance use.

### Laboratory Testing

Drug testing may be a useful part of a complete assessment for an SUD, particularly when a parent or other adult is concerned and the adolescent denies use. As with any laboratory test, this procedure yields limited information and should be used only as an adjunct to the history and physical examination. The use of drug testing in general populations (eg, school drug testing programs) has less utility and many associated ethical and legal concerns. Parents may request that the pediatrician perform a urine drug test; however, testing and sharing of the results should only be done with the permission of the adolescent. If an adolescent refuses a test that is indicated, parents can be coached to implement logical consequences as they would in other circumstances, such as refusal to do homework or chores. If there is concern for harm, then the pediatrician should consider breaching confidentiality. Drug testing

is a complex laboratory procedure with significant potential for false positive and false negative results; the AAP has produced a clinical report to help guide physicians on how to use this procedure most effectively.

### General Care

PCPs are positioned to provide effective care to youth who are using substances, including youth who also need specialty services.

### Reduce Stress

Consider the child's social environment (eg, family social history, parental depression screening, results of any family assessment tools administered, reports from child care or school). Questions to raise might include the following:

*Is an external problem (adverse experience such as abuse, bullying, or family socioeconomic stress) adding to the youth's stress?* Take steps to explore and reduce stressors, as feasible.

*Are the youth's peers using substances?* Explore options to increase healthy social and recreational activities and reduce contact with peers who are using substances. Youth with severe SUDs can be encouraged to change their phone numbers and eliminate old contacts to avoid being contacted by old friends with whom they previously used drugs. Unfortunately, it is impossible to isolate youth with SUDs from substances.

**Table 198-4** Physical Findings Potentially Indicating Substance Use and Abuse

	ACUTE INTOXICATION	CHRONIC IMPAIRMENT	DRUG(S) TO CONSIDER
<b>General Appearance</b>	Altered mood, strange/inappropriate behavior	Poor dress or hygiene	Any drug
<b>Vital Signs</b>		Weight loss	Heroin, cocaine
	Hypertension	Hypertension	Cocaine, amphetamine
	Hypotension, hypothermia		Heroin
	Hyperthermia		Cocaine, amphetamine, ecstasy
	Tachycardia		Marijuana, cocaine, amphetamine
<b>Ears, Nose, and Throat</b>	Conjunctival injection		Marijuana, inhalants
	Dilated pupils		Cocaine, amphetamines
	Constricted pupils		Opioids
	Sluggish pupillary response		Barbiturates
		Nasal irritation	Cocaine, inhalants, opioids (if sniffing)
<b>Cardiac</b>	Arrhythmias	Arrhythmias	Methadone, cocaine, amphetamine
<b>Chest</b>		Gynecomastia	Marijuana, anabolic steroids
<b>Genitourinary</b>		Testicular atrophy, clitoromegaly	Anabolic steroids
<b>Skin</b>		Acne, hirsutism	Anabolic steroids
	Abscesses, needle track marks		IV drug use
<b>Neurologic</b>	Altered sensorium		Any substance
	Ataxia		Alcohol, barbiturates
	Nystagmus		Barbiturates
	Hyporeflexia or hyperreflexia		Marijuana, cocaine, amphetamine

Part of treatment is teaching youths to identify high-risk situations, avoid them when possible, and use strategies to avoid use even when confronted with others who are using. In some communities, youth may be able to attend a recovery high school. Recovery high schools are accredited schools that provide a safe and sober environment for youth with a substance use history to continue their education. Every school has a different approach that includes provision of continued support for students' recovery.

The physician also can acknowledge and reinforce protective factors such as good relationships with at least 1 parent or important adult, prosocial peers, concerned or caring family, help-seeking, and connection to positive organizations.

### Encourage Healthy Habits

Encourage exercise, outdoor time, a healthy and consistent diet, sleep (critically important to mental health), limited screen time, one-on-one time with parents, and time with peers who are not using substances. Offer praise for positive behavior changes, acknowledgment of the youth's strengths, and acknowledgment of the challenges the youth may be facing with transitions including new schools, new friends, new social circles, and new academic demands. Acknowledge that while the patient's friends may be using substances heavily, most of their same-age peers do not binge drink or use drugs.

Encourage involvement in prosocial activities such as youth development, leadership, volunteer, and

after-school activities; sports teams, clubs, and mentoring; and faith-based programs. A strengths-based approach that capitalizes on interests, talents, and future goals is most effective.

### Offer Resources

Helpful resources are included in Tools for Practice: Engaging Patient and Family. Provide contact numbers in case of an emergency.

### Monitor Progress

School reports, as well as youth and parent feedback, can be helpful in monitoring progress.

### Counseling to Reduce Drug Use and High-Risk Behaviors

The strategies described below are common elements of evidence-based and evidence-informed psychosocial interventions for the use of substances. They are applicable to the primary care of youth in the early stages of substance use and to the initial management of youth in more advanced stages while readying them for, or awaiting access to, substance abuse specialty care.

*Tailor intervention to stage of use.* Depending on the screening tool used, levels of risk include abstinence, lower risk (ie, use but no SUD), moderate risk (ie, mild or moderate SUD), high risk (ie, youth with a severe SUD), and acute risk, which is determined as part of the assessment of moderate and high risk youth. Interventions for each stage of change are described in Table 198-5.

**Table 198-5** Substance Use Spectrum and Goals for Office Intervention

STAGE/TRIAGE CATEGORY	DESCRIPTION	OFFICE-BASED INTERVENTION GOALS
Abstinence	No use of drugs or alcohol	<b>Positive Reinforcement</b> Prevent or delay initiation of substance use through positive reinforcement. Include statement about use norms, especially for younger children.
No substance use disorder (SUD)	Use of alcohol or marijuana with peers in relatively low-risk situations; without related problems or interference with domains of functioning—such as school, sports, hobbies, or home life.	<b>Brief Advice</b> Encourage cessation through brief medically based advice, particularly as it relates to patient's future goals. Promote patient strengths.
Mild/moderate SUD	As defined by <i>DSM-5</i> . Adolescents with mild/moderate SUDs typically have associated problems or high-risk behaviors associated with use.	<b>Brief Motivational Intervention</b> Encourage cessation even for a brief trial period if patient is willing. Reduce potential harm by reducing use and focusing on highest-risk behaviors. Encourage parent involvement to help with follow-through. Follow up with primary physician or allied mental health professional to continue conversation and harm reduction.
Severe SUD (addiction)	As defined in <i>DSM-5</i> . Loss of control or compulsive drug use, as "dependence" is defined in <i>DSM-IV-TR</i> .	<b>Brief motivational intervention</b> targeting referral into ongoing treatment. Encourage reducing use and high-risk behaviors and engaging adolescent to accept a referral to treatment. Share diagnosis and referral information with parents, if possible. Follow-up by primary care physician to ensure compliance and encourage long-term treatment.
Acute risk	Use associated with acute risk of overdose or in a situation that is physically risky.	<b>Intervention for safety</b> may include breaching confidentiality to inform parents about use and referral to treatment in a timely fashion. Verbal contracts not to use while awaiting a formal evaluation and advice to parents on how to monitor and what to do in case of escalation may also be helpful.

From Levy SJ, Kokotailo PK. Substance use screening, brief intervention, and referral to treatment for pediatricians. *Pediatrics*. 2011;128(5):e1330–e1340.

**Table 198-6** Sample Framework for Brief Motivational Intervention

PROCESS	DESCRIPTION
Assessment and summary	Targeted assessment for areas of ambivalence to establish rapport and develop a discrepancy between current status and future goals. Sample questions <ul style="list-style-type: none"> <li>• <i>What problems (if any) have you had, related to your use of substances?</i></li> <li>• <i>What regrets (if any) do you have, related to your use of alcohol?</i></li> <li>• <i>What trouble (if any) have you had, related to your use of marijuana?</i></li> </ul>
Brief advice	Offer specific medical advice to quit or cut down substance use as a means for decreasing the types of problems reported during the assessment. Sample statement <ul style="list-style-type: none"> <li>• <i>Only you can decide whether or not to drink alcohol. In regard to your health, I recommend you quit.</i></li> <li>• <i>Having a blackout means that you have had enough alcohol to poison your brain cells, at least temporarily.</i></li> <li>• <i>Kids often make bad choices, like the decision to have sex without a condom, when they are drinking.</i></li> </ul>
Planning	Engage patient in setting personal goals and agenda for change and link to follow-up. Sample statement <ul style="list-style-type: none"> <li>• <i>It sounds like you really enjoy drinking and also don't want to have another blackout. What could you do to protect yourself?</i></li> </ul>

Use motivational interviewing techniques (Table 198-6). The physician can explore ambivalence about use and readiness to enter treatment and negotiate achievable next steps in an empathetic and supportive manner. For high-risk youth, change plans can focus on eliminating highest-risk behaviors (such as driving or riding with an impaired driver) and on engaging in ongoing treatment. The physician should help parents be supportive of behavior change and coach them to avoid inadvertently enabling ongoing use.

If the youth has a history of either driving or being driven by an individual who has been using alcohol, negotiate a safety plan. Students Against Destructive Decisions (SADD) has a Contract for Life that can be signed by both a parent and a youth to ensure that the youth has a plan for a safe ride home.

### Referral to Specialty Treatment

The challenge continually posed to pediatricians is to recognize when a patient's substance use becomes significant enough to warrant referral to a treatment program or facility rather than being treated solely in the primary care setting. The AAP statement regarding screening, brief intervention and referral to treatment (SBIRT) provides specific guidance for when to refer patients and to which level of care. Following is a list of indications for specialty referral:

- Child younger than 15 years with a positive screen for moderate- or high-risk substance use.
- Interventions by PCP have not reduced use.
- Drug use is endangering the youth or others.
- Drug use is threatening the achievement of developmentally important goals, such as school attendance and performance, or relationships.
- Co-occurring mental health disorders are present.
- Youth has a history of trauma.
- Youth is using drugs other than alcohol, marijuana, or tobacco.
- Parents are not involved, do not acknowledge concerns, or one or both parents have an active SUD.

If the child is referred to a specialist, the family will probably need assistance in navigating the requirements of their health insurance plan or the public mental health system and selecting an appropriate

physician. The PCP and specialist will need to reach agreement on respective roles in the youth's care and establish a mechanism for communicating progress. The PCP can support the youth by encouraging his or her positive view of treatment; monitoring progress in care and observing for co-occurring disorders; coordinating care provided by parents, school, medical home, and specialists; and encouraging parents to seek treatment for tobacco use and other dependencies. Resources available to help physicians in these roles are provided in Tools for Practice at the end of this chapter.

Adolescents (and in some cases their parents) may resist treatment of an SUD. In these cases the following steps may be helpful:

- If a referral is clearly indicated, partner with parents to increase the likelihood of follow-through. Clarify with the youth the relevant laws and protections for minors. In many states, parents can file an order with the police to help enforce house rules. Depending on the situation, it may be necessary to involve the designated child protection agency.
- Provide education and motivational counseling to youth (and family, as appropriate) to reduce harm and improve functioning at home. Even if the youth is unwilling to engage with specific substance use treatment, he or she may be willing to see a licensed clinical social worker or psychologist.

### SUMMARY

Primary care pediatricians commonly encounter adolescents whose parents or teachers have concerns about their use of substances, who have signs or symptoms of substance use, or who have a positive screening test for substance use. In adolescents who are known to be using substances or who have other concerning signs or history, PCPs can perform a full assessment, including a physical examination and detailed substance use history. Laboratory testing can be used as an adjunct to the history and physical examination.

PCPs are positioned to provide care to youth who are using substances. PCPs can reinforce strengths and healthy behaviors and, by applying evidence-based brief interventions, can often be effective in preventing these youth from escalating their use of

substances and in motivating them to decrease their use of substances. PCPs can also recognize those youth who need the care of substance abuse specialists, motivate youth and families to connect with needed services, and offer supportive primary care to youth who are involved in specialty care. If youth and their families resist referral for specialty care, PCPs can monitor the youth's progress and provide primary care interventions aimed at reducing substance use and risky behaviors while increasing their motivation to seek specialty care.

## Chapter 199

# SYMPTOMS OF EMOTIONAL DISTURBANCE IN YOUNG CHILDREN

Mary Margaret Gleason, MD

Although the child is the patient, the primary care physician (PCP) must remain vigilant that the child's behavior, particularly with respect to social-emotional problems, may reflect difficulty or dysfunction within the child's caregiving context. This chapter outlines the PCP's role in preventing, identifying, and addressing social-emotional problems in young children—a

role that is critical because of the numerous associated adverse outcomes, including child and family suffering, school failure, mental and physical illnesses, and fractured social networks throughout the lifespan. This chapter focuses on children in the first 5 years of life, using the term *social-emotional problems* to describe the full range of behavioral difficulties, emotional disturbances, and relationship difficulties that may occur in early childhood, especially in the context of adverse childhood experiences. This chapter will refer to the child's primary caregiver as the parents, who may be biologic parents, grandparents, foster parents, or other.

## BACKGROUND AND EPIDEMIOLOGY

During early childhood, social-emotional health develops through a complex interaction of a child's genetic makeup, temperament, and social and physical environment, particularly the primary caregiving relationships. Previously, biological risks were not thought to be easily modifiable. However, recent research demonstrates that a child's environment affects social-emotional development directly and can modify gene expression. This in turn influences the structure of the developing brain. Exposure to a wide range of developmental, behavioral, economic, social, educational, biologic, or family stresses (also known as adverse childhood experiences) can overwhelm the child's ability to cope, alter the brain's architecture, and lead to impaired social functioning and impulse control. Examples of events that may precipitate toxic stress responses include child neglect; physical, emotional, or sexual abuse; exposure to domestic violence; inconsistent parenting; separation from loved ones; impairment of parents or caregivers (eg, chronic parental depression or substance abuse); natural disasters; poverty; unsafe housing; and chronic illness or delays in the child's development. The effect of these stressors on children can vary greatly depending on their developmental stage, their social supports, and the type, intensity, frequency, and duration of the stressors. There is an additive effect of multiple stressors or risk factors, with increased numbers of adverse events related to increased risk of adverse outcomes, likely through the disruption of developmentally normative experiences or the repeated activation of the physiologic trauma responses. Therefore, it is important to identify and ameliorate sources of traumatic stress as early as possible. A study by Egger and Angold demonstrated rates of psychopathology in very young children similar to rates in older children. These disorders can persist and interfere with future development and school readiness.

A child's relationship with caring and nurturing adults is the most critical factor in developing resilience in the face of the normative stresses of childhood and buffering a child from the adverse effects of toxic stresses. Interventions that support the development of positive parent-child interactions can positively influence a young child's brain development, intelligence, and central nervous system hormonal patterns. Specifically, these interventions focus on ensuring that a child experiences sensitive caregiving, in which a caregiver anticipates and responds to a child's unique physical and emotional needs and responds to

a child's positive and negative behaviors consistently, persistently, and contingently. Beginning in infancy and continuing through childhood and into adolescence, parents and other caregivers can support their child's pro-social behaviors and emotional regulation by modeling and reinforcing these behaviors and helping a child organize emotions in response to challenging situations. The foremost role of the PCP is in primary prevention—supporting parents and fostering childhood resilience to buffer against the negative effects of toxic stress (topics addressed in the Institute of Medicine *From Neurons to Neighborhoods: The Science of Early Childhood Development*, *Bright Futures*, Substance Abuse & Mental Health Services Administration reports, and the American Academy of Pediatrics (AAP) Policy Statement on Toxic Stress, among others).

## Role of the Primary Care Physician

The PCP can collaborate with local community partners (eg, developmental-behavioral pediatricians, early childhood mental health professionals, early intervention professionals, early childhood educators in child care and schools, child advocates, and public health agencies) to identify and address stressors that put children in their community at high risk for social-emotional problems and to identify and strengthen protective factors. A summary of approaches for screening strategies and interventions can be found on the AAP Early Brain and Child Development Web site ([www.aap.org/en-us/advocacy-and-policy/aap-health-initiatives/EBCD/Pages/default.aspx](http://www.aap.org/en-us/advocacy-and-policy/aap-health-initiatives/EBCD/Pages/default.aspx)). Each group of PCPs and other early childhood partners will address the issues unique to their community, but some examples may include advocating for the creation of safe outdoor spaces for children's exploration, for domestic violence shelters, for evidence-based nurse visitation programs, for increased access to Head Start or other enriched early childhood caregiving environments, or for appropriate access to prenatal care and postnatal nutrition. Universal prevention approaches also occur within the primary care practice. Physicians can create an environment in which parents feel comfortable raising questions about emotional or behavioral concerns by asking about social-emotional development with open-ended questions, including these topics as part of anticipatory guidance, and including literature promoting social-emotional well-being in the waiting room. For children with overt social-emotional problems, PCPs are often the first professionals who identify the problem as a clinical issue that warrants attention. Therefore, they are responsible for supportive communication about the concern, as well as collaborating with their community partners to enhance access to specialty treatment and monitoring treatment effects.

## Findings Suggesting Social-Emotional Problems or Risk Factors for Problems

The symptoms that suggest social-emotional problems for children younger than 5 years can be identified in the child, the caregiver, or the relationship between the child and caregiver. A summary of some

### BOX 199-1 Symptoms and Clinical Findings Suggesting Social-Emotional Problems in Children Younger Than 5 Years

#### CONCERNS ABOUT THE CHILD'S BEHAVIOR OR EMOTIONS

- Child has regulatory difficulties evidenced by difficulty calming, irregular sleep or feeding patterns, or excessive sensitivity to sensory experiences.
- Child demonstrates difficulty organizing behaviors and demonstrates extreme aggression or severe or persistent tantrums that involve injury or damage to objects.
- Child has experienced significant difficulty adjusting to child care or preschool or has been expelled from child care or preschool.
- Child's activity and impulsivity levels are excessive for developmental age.
- Child's mood is unhappy, irritable, or lacking in true joy more frequently than the average child.
- Child shows more anxiety than others his age, especially related to specific triggers or traumatic reminders, separation from caregiver, or experiencing new situations.
- Child will not talk in public even with reassurance.
- Child has excessively rigid behavioral patterns or "habits" that interfere with typical functioning.

#### CONCERNS ABOUT CAREGIVER

- Caregiver is unable to consider the child's strengths, becomes disorganized when talking about the child, or talks about the child using only a negative tone.
- Caregiver does not anticipate a child's need for comfort or does not offer appropriate comfort in new situations or times of distress.

- Caregiver is excessively protective of child and does not allow developmentally appropriate exploration.
- Caregiver is or has been abusive or neglectful (eg, involvement with child protection).

#### CONCERNS ABOUT RELATIONSHIP

- Child does not or cannot elicit comfort or reassurance effectively from caregiver in times of distress (eg, immunizations or separations).
- Child (older than 9 months [developmental age]) does not look to caregiver in novel situations or to share joy or excitement.
- Child does not manifest age-appropriate stranger anxiety.
- Child has not met appropriate social milestones related to social reciprocity, peer interactions, adult interactions, or focused attachment (comfort-seeking) behaviors with a primary caregiver.
- Child's relationship with caregiver has been disrupted (eg, foster care, military deployment of parent, death of parent).

#### RISK FACTORS FOR INCREASED SUSCEPTIBILITY

- History of maltreatment or significant caregiving disruption (such as is seen in children in foster care, those who have been adopted, or those with other caregiving disruptions)
- Family stressors (eg, poverty, divorce, single parenting, unemployment, limited access to health care, lack of safe and affordable housing or food, social isolation, community violence)
- History of adverse childhood experience in parents
- Parental substance abuse, mental illness, or domestic violence

the clinical findings that may indicate the need for further assessment can be found in Box 199-1.

#### Tools to Assist With Identification

Validated, standardized screening instruments may be used to identify children at high risk for having social-emotional problems, either because of parent-reported symptoms or the caregiving environment. Table 199-1 provides examples of general psychosocial screening instrument results that may suggest a child has social-emotional problems. Negative screens indicate that a child is within a lower-risk group, and can be an opportunity for positive feedback or may guide anticipatory guidance. A negative screen should not override clinical judgment if a PCP has concerns because of history or observations. With all parent report measures, but especially in early childhood mental health, it is particularly important to recognize that a parent report reflects that parent's perception of the child's behaviors. Positive screens may indicate that the child has a mental health problem, that the parent is experiencing extreme distress (because of the child or

another cause), or that there is a problem within the relationship between the parent and the child. All 3 possibilities have implications for the child's development and warrant clinical attention. Therefore, a positive screen should be followed by further assessment to determine more about the clinical concern.

#### ASSESSMENT

Assessment begins by differentiating the child's symptoms from normal behavior. Children vary in temperament and in their capacity to self-regulate and adapt. Virtually all young children exhibit challenging behaviors at times, especially during periods of adjustment to new environmental circumstances such as birth of a sibling, a move, a new child care arrangement, or a family crisis. Children with social-emotional problems may experience more severe and persistent emotional or behavioral reactions to these normative stresses or even in the absence of an acute stressor. There are also some conditions that may mimic or co-occur with social-emotional problems of young children. Table 199-2 provides a summary of these conditions.

**Table 199-1** General Psychosocial Screening Results Suggesting Social-Emotional Problems

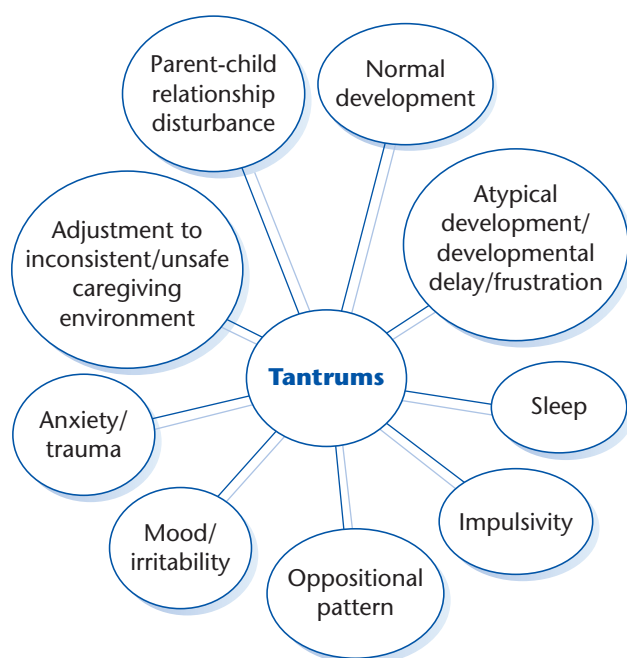

SCREENING AREA	SCREENING INSTRUMENT	SCORE
Child	Baby Pediatric Symptom Checklist (B-PSC) (irritability, inflexibility, difficulties in parenting)	A score of 3 or above is considered positive.
	Preschool PSC (internalizing, externalizing, attention, and parenting challenges)	A score of 9 or above is considered positive.
	Early Childhood Screening Assessment (assesses emotional and behavioral development in young children 18–60 months old and maternal distress)	A score of 18 or higher on items 1 through 36 indicates a higher than usual risk of disorder. A score above 1 on 37 or 38 may reflect parenting stress. A score of at least 1 on items 39 or 40 suggests risk of caregiver depression. Each measure includes specific instructions about cutoff score for that age.
Environment	Ages & Stages Questionnaire: Social-Emotional (ASQ:SE) (useful as early as 4 months to screen for problems in caregiver-infant bond and interaction)	Each measure includes specific instructions about cutoff score for that age.
	Edinburgh Postpartum Depression Scale	Score of 12 or above is considered positive.
	Parent Health Questionnaire-2	Any positive response is considered positive.
	Abuse Assessment Screen	Positive response to any question indicates high risk of interpersonal violence.
	Safe Environments for Every Kid (SEEK)	Positive responses suggest presence of family stressors.
	Caregiver Strain Questionnaire	Score of 7 or more suggests high level of caregiver strain.
	Bright Futures Surveillance Questions	Answers suggest social-emotional stressors.
	Parenting Stress Index	Results suggest high levels of stress associated with parenting, or within the parent-child relationship.

**Table 199-2** Differential Diagnosis of Extreme Emotional or Behavioral Dysregulation

DOMAIN	DIFFERENTIAL DIAGNOSIS	RATIONALE
Normal development Developmental delays/frustration	Cognitive and language disabilities	Extreme responses to normal limits, fatigue, hunger, or new situations are part of typical development in the third and fourth years of life.
	Hearing or vision problems	Children with language deficits may experience frustration expressing their needs and desires and therefore may exhibit symptoms of social-emotional problems. Children with intellectual disabilities may function at a level younger than their chronological age and size. This gap between their ability and adult expectations for their behaviors can lead to frustration for the child and caregiver.
	Autism spectrum disorders (ASDs)	All children who are manifesting atypical development or behavior should be screened for sensory deficits. A complete hearing assessment should be obtained for all young children with delay in language development. Children with ASDs have problems with social relatedness (eg, poor eye contact, preference for solitary activities, lack of joy in sharing with others, lack of empathy), language (delayed expressive language or unusual syntax or prosody), limitations in their range of interest (persistent and intense interest in a particular activity or subject), or atypical mannerisms that can interfere with their ability to function. They may have a need for routine and can become anxious or angry if a routine is disrupted. Accordingly, these children may manifest symptoms of social-emotional problems. In addition, children with ASDs are also at higher than usual risk of comorbid psychiatric disorders that may present in early childhood.
Regulatory problem	Sleep problems Feeding disorders	Sleep deprivation as a result of bedtime struggles, night waking, or obstructive sleep apnea can cause irritability and behavioral problems; conversely, social-emotional problems can cause sleep difficulties. Difficulties with feeding—either refusal, sensitivities, or overeating—can cause disruptive or distressed patterns in an infant or toddler, which can occur in a mutually escalating cycle with parental distress around the eating patterns.

**Table 199-2**      **Differential Diagnosis of Extreme Emotional or Behavioral Dysregulation—cont'd**

DOMAIN	DIFFERENTIAL DIAGNOSIS	RATIONALE
Child disruptive behavior problem	Attention-deficit/hyperactivity disorder (ADHD)	High levels of impulsivity, as well as inattentiveness and distractibility, may be seen in very young children with ADHD. It is especially important to assess whether the symptoms occur in multiple settings (as required in ADHD) or whether they are specific to a context or relationship, a pattern that would likely represent an adjustment to that situation. Because of the range of normal activity levels in very young children, ADHD must be distinguished from developmentally inappropriate expectations for young children and from parental symptoms that make normal child behaviors less tolerable, such as depression. In addition, symptoms suggestive of ADHD should be distinguished from lead toxicity and effects of medications such as steroids or sympathomimetics.
	Disruptive behavior disorders (oppositional defiant disorder, conduct disorder)	Disruptive behaviors in young children may present with extreme oppositional behaviors or conduct disorder symptoms, including aggression. These can occur when a child experiences an inconsistent or coercive caregiving environment.
Child mood symptoms	Depression	Very young children can present with all of the symptoms of major depressive disorder, and this diagnosis should be considered in children with extreme sadness or irritability. Associated symptoms include sleep and appetite changes, play or talk centered around death and dying, decreased joy in playing, and concentration difficulties. The validity of the diagnosis of bipolar disorder in preschool has not yet been established.
Child anxiety	Anxiety disorders	Preschoolers may present with general anxiety, extreme separation anxiety, school avoidance behaviors, and selective mutism, all often accompanied by extreme distress in the face of the trigger. Similarly, very young children with obsessive-compulsive behaviors may present with behavioral symptoms when asked to interrupt a compulsive behavior.
	Post-traumatic stress disorder and other trauma-related symptoms	In addition, children who have experienced traumatic events may exhibit a set of symptoms similar to the presentation of post-traumatic stress disorder seen in older children (re-experiencing the trauma in thoughts, speech, play, and dreams; emotional and physiologic hyperarousal to reminders of the trauma; avoidance of reminders of the trauma; and numbing symptoms). It is not uncommon for children who have experienced traumatic events to present with disruptive behaviors, perhaps related to their own inability to organize their reactions or because of less consistent parenting after the traumatic event.
Parent-child relationship disturbances	Parental mental health problems, substance abuse problems, or severe cognitive limitations	Young children who experience unpredictable or inconsistent parenting, especially if it includes neglectful or dangerous experiences, may present with inconsistent and sometimes dangerous behaviors. Treatment for parents and consideration of child protection involvement is critical in addressing these clinical scenarios. These patterns should be considered in children with a history of foster care or adoption. Depression or other mental illness, bereavement, substance abuse, cognitive disability, or disadvantaged socioeconomic circumstances may prevent a child's caregiver(s) from nurturing the child effectively and may contribute to social-emotional problems in the child.
	Disordered attachment or parent-child relationship difficulties	The bond between a child and his caregiver can be affected by characteristics of the child, caregiver, or temperamental "goodness of fit" between child and caregiver. Manifestations of a suboptimal parent-child relationship that increases the risk of attachment problems may include ineffective or inconsistent soothing, nurturing, or disciplinary behaviors of the caregiver, or lack of responsiveness of the child to his caregiver's soothing and nurturing efforts. A parent's own history of unsafe relationships (as a child or in romantic relationships) may shift how a parent thinks about herself in the intimate relationship of parenting and how the parent experiences the child's behaviors and needs. Relationship difficulties may present in the clinic with a parent who experiences the needs of her child as excessive or troublesome, with a child who develops a pattern of maladaptive ways of engaging the parent's attention, or with a child who does not seem to make any attempts to engage the parent even when he might be expected to need comforting.

**Figure 199-1** Differential diagnosis of emotional or behavioral dysregulation.

Extreme temper tantrums or emotional or behavioral responses to small events such as limit setting can reflect a range of clinical issues. Figure 199-1 provides categories of possible child, parent, or relationship difficulties that should be considered when a parent reports concerns about the child's emotional or behavioral development. Importantly, it should be considered that a maladaptive behavior often represents the only set of tools a child has to cope with an overwhelming emotion, such as anxiety, frustration (with self or other), or distress. Additionally, it is important to address parental concern about social, emotional, or behavioral patterns, even if the PCP does not identify atypical development. Providing parental support around parenting stresses, wondering about alternative attributions for behavior, strategizing around safe, consistent, nurturing responses to difficult behaviors, and close follow-up all may be helpful.

The special circumstance of a chronic or significant medical problem should be considered, as it may trigger social-emotional problems in a range of domains. Young children with chronic medical problems are more likely to experience developmental delays and traumatic experiences in the form of medical procedures and separations from parents, and may be seen as particularly vulnerable by their parents because of their medical condition. They may also take medications that may affect mood regulation (eg, steroids) or have primary central nervous system lesions that interfere with emotional, behavioral, or developmental regulation. Similarly, although all children with growth failure should be evaluated for underlying medical problems, psychosocial growth failure can occur in the context of an inadequate caregiving environment, and the role of the caregiving environment as a

protective or risk factor should be considered in all cases of growth failure. (See Figure 199-1.)

If a child or caregiver seems to be experiencing symptoms, the PCP can further assess for problems by collecting further information, refer to an appropriate specialist, or review diagnostic criteria for symptoms of disorders in the caregiver-child relationship.

The PCP can information from other caregivers, child care centers, and preschool about eating, sleeping, irritability, and aggression with peers, using behavior or food diaries or validated, structured measures, such as the Baby PSC, Preschool PSC, or Early Childhood Screening Assessment.

Referral may be to a developmental-behavioral pediatrician, mental health professional with expertise in assessment of young children and their families, or early intervention agency.

## PLAN OF CARE FOR CHILDREN WITH SOCIAL-EMOTIONAL PROBLEMS

The care of a child experiencing social-emotional problems can begin in the primary care setting. Universal screening or active surveillance for social-emotional problems can create an environment in which families feel comfortable discussing social-emotional issues. Following are the elements of providing care to a child with social-emotional problems identified in the primary care setting.

### Celebrate the Strengths and Engage Child and Family in Care

Physicians can engage families by recognizing and reinforcing the strengths of child and family and also by acknowledging the distress and emotional costs of the social-emotional concern. The PCP can acknowledge and reinforce protective factors (eg, good relationships with at least 1 parent or important adult, pro-social peers, concerned or caring family, help-seeking, or connection to positive organization[s]). In fostering engagement, it can be useful to use "common factors" techniques to build trust and optimism, including reaching agreement on incremental next steps and, ultimately, therapeutic goals, developing a plan of care (see the following clinical guidance), and determining the role of the PCP. The PCP's role may include providing intervention(s); providing initial intervention while awaiting family's readiness for or access to specialty care; collaborating with a specialist; coordinating with specialist(s), child care, school, or agencies; monitoring progress; and supporting the family's engagement in treatment. Without engagement, most families will not seek or continue in specialty mental health care. This process may require multiple primary care visits.

### Promote Safety

Families whose children experience social-emotional difficulties are at particularly high risk of exposure to unsafe situations. These may include family partner violence, child abuse, or community exposure to violence. In addition, some families may experience safety risks related to housing conditions or a child's access to potentially dangerous medications (diabetes

medications, sleeping medications, antihypertensive agents). Assessment for other risks, including weapons in the home, is an important role of the PCP.

### Address Basic Needs

Identifying families' basic needs is perhaps the most important universal intervention for all children with social-emotional problems. Family distress may be reduced by identifying and supporting families with basic needs issues, such as housing, child care, or access to food and a safe place to sleep. Without addressing these needs, it is unlikely that mental health referrals will be successful.

### Support Parental Mental Health

Whether a parent is experiencing a clinical-level problem or distress related to sleep deprivation, it is important for a parent to experience clinical interactions with the PCP as supportive. Even when there are concerns about specific parenting approaches, families will consider changing their behaviors only if they feel that the clinical approach is helpful and that their perspective is respected. Discussion of parental clinical mental health issues like depression or substance abuse, including those identified by screening, may be an important clinical step toward addressing the child's emotional needs.

### Reframe the Child's Behaviors

When a parent seems to perceive a child as overwhelmingly negative or interprets developmentally typical behaviors as intentionally disruptive to the parent, it can be helpful to reframe the behaviors in a way that may allow the parent to experience the same behaviors differently. For example, reframing "clingy and needy" behaviors in toddlers as demonstrating that they are using a parent for emotional support as they begin to venture out to explore their environment may be helpful. Using handouts such as those found on the AAP Early Brain and Child Development resource page or the Circle of Security handout ([circleofsecurity.org](http://circleofsecurity.org)) or video ([www.youtube.com/user/CircleOfSecurity](http://www.youtube.com/user/CircleOfSecurity)) may be helpful and efficient ways to inform parents. It is important to note that telling a parent the child's behavior is "normal" without putting it into a developmental or emotional context may be experienced as rejecting by parents who are worried about their child.

### Encourage Consistency in Child's Caregiving Environment

No matter what the clinical concern, children will benefit from predictable, consistent, and safe responses to both pro-social and negative behaviors. The PCP can encourage the primary caregivers to reflect on and enhance their own consistency. In addition, the PCP can assist the primary caregivers in developing strategies to increase the consistency the child experiences across caregivers, including mother, father, grandparents, babysitters, and child care providers.

### Explore Opportunities for Positive Parent-Child Interactions

Whether a clinical problem seems to be located primarily within the child, the parent, or their relationship,

it is likely that all family members are experiencing less joy and fulfillment from their interactions than they would like. Assisting a parent in identifying a child's strengths and positively reinforcing positive behaviors or efforts toward positive behaviors can be a useful first step toward healing. "Time in," as little as 5 minutes a day of interactive play time with the child, can be a way for parents to delight in their child, feel competent, and appreciated, and for the child to enjoy the parent. If a caregiver's own history of problematic relationships or mental health problems is affecting her relationship with the child, it can be useful to explore her readiness to address these problems as part of helping the child.

### Encourage Healthy Habits and Activities

The PCP can encourage healthy child and family habits that will provide a sound foundation for ongoing development. These healthy habits can include opportunities for active play, good nutrition, media-free family meals, regular bedtime routines, and adequate sleep. Discussions of media exposure and the dangers of frightening or violent media can be especially important for parents of children with anxiety, aggressive behaviors, or a history of trauma exposure. Additionally, the AAP media recommended limits to screen time can promote healthy brain development, increase interactive and exploration time, and reduce the potential for exposure to adult content or violence.

The PCP can direct the parent toward high-quality early childhood care and education such as Head Start and programs accredited by the National Association for the Education of Young Children (NAEYC). The PCP can also encourage communication between child care or preschool personnel and home and coach them to praise progress and effort, not just outcomes. The AAP Early Brain and Child Development Resources can be shared with parents to give to child care providers to promote consistency across a child's environments.

### Offer Initial Intervention(s)

Evidence-based psychosocial interventions for social-emotional problems include a number of "common elements" amenable to implementation in the primary care setting. Table 199-3 provides strategies that the physician can suggest to the family.

### Provide Resources

Helpful handouts, fact sheets, and Web sites are included in Tools for Practice at the end of this chapter.

### Monitor Progress

Symptoms can be tracked using screening measures described in Table 199-1 or disorder-specific measures. Nonproprietary general measures like the Baby and Preschool Pediatric Symptom Checklists and the Early Childhood Screening Assessment, or the proprietary Strengths and Difficulties Questionnaire, are useful in monitoring symptoms over time. Symptom-specific measures like the Eyberg Child Behavior Inventory (disruptive behaviors), and the Preschool Feelings Checklist (depression) are valuable and validated

**Table 199-3** Strategies for Building Child's Social-Emotional Skills and Resilience and in Addressing Behavior Problems

STRATEGY	ADVICE TO CAREGIVERS
Promote daily positive joint activities between parent(s) and child.	<ul style="list-style-type: none"> <li>• Enlist support of extended family, friends, faith group, or involved agency to relieve parent of some stresses and provide emotional support.</li> <li>• Educate about the importance of smiling with and talking and cooing to infants, attending to vocalizations or speech, and reading and playing at all ages.</li> <li>• Assist with recognizing a child's cues by labeling the child's behaviors and needs in the office and support the parent in responding sensitively.</li> <li>• Increase parent's one-on-one time with child (eg, interacting, feeding, reading, playing). Daily routines around mealtime and bedtime, for example, can ensure that these activities are well integrated into family life.</li> <li>• Promote resilience at every visit by using the anticipatory guidance of Bright Futures or the EBCD website and by emphasizing individual strengths.</li> </ul>
Apply positive parenting principles to toddlers and pre-schoolers (positive attention for positive behaviors; removing attention for low-level behaviors; and safe, consistent, calm consequences for unacceptable or unsafe behaviors).	<ul style="list-style-type: none"> <li>• Reinforce desired behaviors using parental attention (eg, "Catch them being good").</li> <li>• Help the child develop vocabulary to describe feelings.</li> <li>• Encourage praise and reinforcement ("rewards") for specific, desired (target) behaviors. The choice of target behaviors and the time intervals for reinforcements should be developmentally appropriate and sustainable.</li> <li>• Teach parents to reduce attention to ("ignore") minor, provocative behaviors. "Pick battles" and focus discipline on priority areas.</li> <li>• Reduce positive reinforcement of disruptive behavior.</li> <li>• Teach parents to recognize the child's anxiety, expose the child only to manageable anxiety-provoking situations, provide support around unavoidable anxiety-provoking situations, and praise the child's management of her feelings.</li> <li>• When possible, reorganize the child's day to avoid trouble by avoiding situations in which the child cannot control himself or herself. Examples include asking a neighbor to look after the child while the parent goes shopping, ensuring that activities are available for long car journeys, and arranging activities in separate rooms for siblings who are prone to fighting.</li> <li>• Talk to the child care center or preschool and suggest that similar principles be applied.</li> </ul>
Encourage parents to be calm and consistent.	<p>Suggest that parents do the following:</p> <ul style="list-style-type: none"> <li>• Set clear house rules agreed on by the primary caregivers</li> <li>• Give short, specific commands about the desired behavior, not prohibitions about undesired behavior (eg, "Please walk slowly," rather than "Don't run").</li> <li>• Provide consistent and calm consequences for misbehavior. Consequences should not be dangerous, drastic, or of extreme duration.</li> <li>• Use natural consequences, such as the child cleaning up a mess he or she has created.</li> <li>• When enforcing a rule, avoid getting into arguments or explanations, reduce additional attention for the misbehavior, and defer negotiations until periods of calm.</li> <li>• Consider parenting classes or community support.</li> </ul>

measures that provide more specific information about a child's course. Child care or preschool reports can be helpful in monitoring progress. Attention-deficit/hyperactivity disorder (ADHD) can be tracked using measures validated on older children, such as the Vanderbilt ADHD Rating Scales and the Conners-3. More extensive measures, such as the Child Behavior Checklist, are validated in children as young as 18 months of age, but are longer than a PCP can use regularly.

### Involve Specialist(s)

Involvement of a specialist may be considered appropriate under the following circumstances:

- A child younger than 5 years has symptoms of social-emotional problems causing functional impairment or distress; for example
  - The child has symptoms of anxiety, sadness, or irritability that limit participation in family

interactions, child care experiences, or other normative experiences.

- The child has behaviors that are disruptive in the home or in out-of-home settings, or that limit participation in developmentally appropriate experiences.
- The child does not use the caregiver effectively for emotional support or is indiscriminate in social interactions with strangers.
- The child exhibits sleep or eating problems are not responsive to primary care interventions.
- The parent is very negative toward child, compromised by physical or mental illness, disengaged, inconsistent in providing nurturing, or unresponsive to primary care guidance.
- The parent has difficulty allowing a child to have developmentally appropriate opportunities for exploration.

**Table 199-4** Psychosocial and Psychopharmacologic Treatments for Social-Emotional Problems in Young Children

### EVIDENCE-BASED PARENTING PROGRAMS

CLUSTER AREA	PARENTING PROGRAM
For disruptive behavioral problems	<ul style="list-style-type: none"> <li>• The Incredible Years (<a href="http://www.incredibleyears.com">www.incredibleyears.com</a>)</li> <li>• Triple P Positive Parenting Program (<a href="http://www.triplep.net">www.triplep.net</a>)</li> <li>• Parent-Child Interaction Therapy (<a href="http://pcit.php.ufl.edu">http://pcit.php.ufl.edu</a>)</li> <li>• “Helping the Noncompliant Child” parent training program (<a href="http://www.strengtheningfamilies.org/html/programs_1999/02_HNCC.html">www.strengtheningfamilies.org/html/programs_1999/02_HNCC.html</a>)</li> <li>• Nurse-Family Partnership (<a href="http://www.nursefamilypartnership.org">www.nursefamilypartnership.org</a>)</li> </ul>
For first-time, pregnant, low-income women prior to 28 weeks’ gestation	
For children in foster care	<ul style="list-style-type: none"> <li>• Attachment and Biobehavioral Catch-up (<a href="http://www.cachildwelfareclearinghouse.org/program/108/detailed">www.cachildwelfareclearinghouse.org/program/108/detailed</a>)</li> <li>• Multidimensional Treatment Foster Care Program for Preschoolers (<a href="http://www.uoregon.edu/~snaplab/SNAP/Projects.html">www.uoregon.edu/~snaplab/SNAP/Projects.html</a>)</li> <li>• Parent Child Interaction Therapy<sup>a</sup></li> </ul>
For parent-child relationship disturbances and high-risk parenting situations	<ul style="list-style-type: none"> <li>• Circle of Security (<a href="http://www.circleofsecurity.org">www.circleofsecurity.org</a>)</li> <li>• Promoting First Relationships (<a href="http://www.pfrprogram.org">www.pfrprogram.org</a>)</li> <li>• Parents as Teachers (<a href="http://www.parentsasteachers.org">www.parentsasteachers.org</a>)</li> <li>• Child Parent Psychotherapy</li> </ul>
For children exposed to trauma, including sexual abuse or domestic violence	<ul style="list-style-type: none"> <li>• Child Parent Psychotherapy (<a href="http://www.cachildwelfareclearinghouse.org/program/49/detailed">www.cachildwelfareclearinghouse.org/program/49/detailed</a>)</li> <li>• Cognitive behavioral therapy<sup>b,c,d</sup></li> </ul>

### PSYCHOPHARMACOLOGIC INTERVENTIONS<sup>E</sup>

There is limited evidence to support psychopharmacologic intervention in this age group. There is a single multisite, placebo-controlled, randomized trial of methylphenidate and another focused on atomoxetine as a treatment for attention-deficit/hyperactivity disorder in preschoolers. Both showed the medication was more effective than placebo, but less effective than in older children and was associated with a higher rate of adverse effects.<sup>f,g</sup>

Updates are available at [www.aap.org/mentalhealth](http://www.aap.org/mentalhealth).

- The family is not able to maintain a calm, consistent, or safe environment. (In this instance, also consider reporting to child protective services.)

When specialty care is needed, a PCP should recommend evidence-informed treatment. A variety of evidence-based and evidence-informed psychosocial interventions are available for the treatment of social-emotional problems in children younger than 5 years of age. See Table 199-4.

No randomized controlled trials of medications have been carried out in young children with disruptive behavior, mood, or anxiety disorders, but ADHD has been studied using 2 different medications (methylphenidate and atomoxetine). Current evidence suggests that these two agents have higher rates of adverse effects in preschoolers than are reported in older children.

The PCP and specialist(s) should clarify roles in the child’s care. The PCP’s role may, for example, include engaging and encouraging the family’s positive view of interventions or referral and serving as the care coordination “hub” of the medical home. The specialist may monitor the child and family’s progress, observe for and addressing any comorbidities that may develop, and coordinate care provided by parents, child care center, preschool, medical home, early intervention agency, and specialists.

## Chapter 200 SYNCOPE

Prema Ramaswamy, MD

### DEFINITION

Syncope, defined as a transient sudden loss of consciousness and postural tone, is a fairly common complaint in children, particularly adolescents. Pre-syncope is the presence of sensory and postural impairment without the actual loss of consciousness. The origin of the word *syncope* is a Greek term meaning *to cut short* or *interrupt*. Regardless of the underlying disorder, syncope is caused by interruption of essential energy substrates to the brain, usually from a transient reduction in cerebral blood flow. In children and adolescents, syncope is most often benign; however, in rare cases, it can be a first signal of potential sudden death, and hence identifying patients at risk is critical. Even when the cause is benign, syncope can result in injury, and it certainly provokes anxiety.

Although the exact incidence of syncope in children is not known, it affects 3.5% of the general adult population. Almost one-third of these adults will have recurrent syncope. The corresponding numbers for children are not known, but recurrence seems to be less common in childhood.

### CAUSES OF SYNCOPE

The most common cause of benign syncope is neurocardiogenic or vasovagal syncope, also termed the common faint, church faint, reflex syncope, or neurally mediated syncope (NMS). Another common cause of benign syncope is orthostatic hypotension. Together, these 2 causes are even more common in adolescents than in adults, and account for almost 80% of all cases. Both causes are more common during adolescence than at any other time in childhood. Syncope is also common in children from 6 months to 3 years of age, when breath-holding spells are prevalent. In particular, children with the pallid type of breath-holding spell have an increased risk for NMS as adults. Syncope that is not benign can stem from cardiac, neurologic, metabolic, and psychiatric causes. Box 200-1 lists the causes of syncope.

### Neurally Mediated Syncope

Naturally mediated syncope is classified into 3 types

1. *Central syncope* occurs in response to strong emotional stimulation such as pain, anticipated pain, or the sight of blood. In susceptible individuals, emotional stimulation can activate ill-defined areas within the central nervous system that, in turn, trigger sympathetic inhibition and parasympathetic activation.
2. *Postural syncope* is associated with the upright position, typically developing while the person is standing or walking. It is the most common type of NMS, much more frequent than central or situational syncope.

**BOX 200-1 Causes of Syncope****NEURALLY MEDIATED SYNCOPE**

- Emotional
- Postural
- Situational
  - Deglutition syncope
  - Micturition syncope
  - Weight-lifter's syncope
  - Defecation syncope
  - Carotid sinus hypersensitivity
  - Hair-grooming syncope

**ORTHOSTATIC HYPOTENSION**

- Primary
- Drugs
- Pregnancy
- Adrenal insufficiency
- Systemic mastocytosis
- Familial dysautonomia
- Postural orthostasis tachycardia syndrome

**BEHAVIORAL OR PSYCHIATRIC**

- Hyperventilation
- Hysteria, conversion reaction
- Breath-holding spells
- Cyanotic
- Pallid infantile syncope

**NEUROLOGIC**

- Seizure
- Migraine

- Trauma, concussion
- Narcolepsy

**CARDIAC**

- Structural abnormalities
  - Aortic stenosis
  - Hypertrophic cardiomyopathy
  - Tetralogy of Fallot
  - Pulmonic stenosis
  - Primary pulmonary hypertension
  - Coronary artery abnormalities
  - Marfan syndrome
- Arrhythmia
  - Bradycardia
  - Sick sinus syndrome
  - Atrioventricular block
  - Supraventricular tachycardia
  - Ventricular tachycardia, fibrillation
    - Myocarditis, pericarditis
    - Postoperative cardiac surgery
    - Prolonged QT syndrome

**METABOLIC**

- Hypoglycemia
- Anemia

3. *Situational syncope* occurs after the specific stimulation of sensory or visceral afferents, resulting in hypotension and then syncope. Examples include syncope evoked by the hypersensitivity of carotid baroreceptors, micturition syncope, defecation syncope, hair-grooming syncope, swallow syncope, cough syncope, and weight-lifter's syncope, all of which have been described in teenagers but are much less common than in adults.

**Pathophysiologic Features**

Although the pathophysiologic mechanism of NMS continues to be debated, investigators think it occurs in persons with a predisposition when they experience peripheral venous pooling and a fall in venous return. An increase in catecholamine release follows as a compensatory mechanism. The primary abnormality in patients who faint is unclear but may include  $\beta$ -adrenergic hypersensitivity, resulting in a relatively empty hypercontractile heart. Cardiac mechanoreceptors are stimulated, producing the Bezold-Jarisch reflex—a vagal response that includes sinus bradycardia, hypotension, and peripheral vasodilation. The syncope is termed *vasodepressor* if the more prominent element is hypotension, and *cardioinhibitory* if

bradycardia is more prominent. In most instances, the syncope is mixed, with both hypotension and bradycardia.

**Clinical Manifestations**

In NMS of childhood, loss of consciousness is typically preceded by light-headedness, nausea, yawning, a feeling of being hot, and sounds seeming distant to the ear. Typically brief (from a few seconds to 1 or 2 minutes), the loss of consciousness is most often brought about by pain or by prolonged standing, especially in warm environments such as in a crowded room or in a hot shower. Occasionally, the cause is not identifiable. Symptoms characteristically appear after the person has been upright for at least a few minutes, in contradistinction to the patient with orthostatic hypotension, whose symptoms occur within seconds of standing.

**Orthostatic Hypotension**

Orthostatic hypotension is the fall in blood pressure after assuming the upright position. The autonomic nervous system provides the principal responses to changes in position. When a person stands, cardiac output and cerebral perfusion are maintained by a

combination of pumping action of skeletal muscles, venous valves, and carotid baroreceptor-mediated arterial constriction and cerebral autoregulation. If these mechanisms are unable to maintain the blood pressure, then the decrease in the pressure in the carotid sinus leads to reduced afferent traffic in the carotid sinus and thus to an increase in the heart rate. The compensatory increase in heart rate is inadequate in patients with orthostatic hypotension, and symptoms of weakness and light-headedness develop, typically within seconds of standing. The sinus tachycardia of orthostatic hypotension sets this type of syncope apart from NMS, during which bradycardia is a prominent sign.

Volume depletion from any cause, but in children most often from vomiting and diarrhea, will exacerbate orthostatic hypotension. Drugs that cause vasodilation and diuretics can also stimulate orthostasis.

Pregnancy should always be considered when a woman of childbearing age faints; pregnancy-associated fainting results from increased estrogen and progesterone levels that cause decreased peripheral vascular resistance and hypotension.

In the past few years, an entity called the postural orthostasis tachycardia syndrome (POTS) has been described. The diagnosis of POTS requires orthostatic heart rate acceleration in excess of 120 beats per minute or an absolute increase of 30 beats per minute or greater in the absence of significant orthostatic hypotension. Two forms have been identified. In the more common peripheral variety, persistent tachycardia, associated with fatigue, exercise intolerance, and palpitations, is present while the patient is upright. The onset may occur after a viral illness, trauma, or surgery. The second type of POTS, the  $\beta$ -hypersensitivity (or central) form, is often associated with migraines, tremor, and excessive sweating. Both forms are more common in young women, and treatment can be frustrating.

Familial dysautonomia, an inherited autosomal recessive condition with abnormalities of the autonomic nervous system, is a rare but serious cause of orthostatic syncope, with affected patients at risk for sudden death.

### Behavioral or Psychiatric Causes of Syncope

#### Breath-holding Spells

Two types of breath-holding spells typically occur in children between 6 months and 3 years: cyanotic and pallid. In the former, an episode of cyanosis and apnea is precipitated after a child is upset and begins to cry. Stiffening of the body and a loss of consciousness may soon follow. Although the pathophysiologic basis is unclear, crying during expiration may cause increased intrathoracic pressure, which, in turn, leads to low cardiac output. Hypoxia combined with decreased cerebral blood flow leads to the loss of consciousness. The event is brief, and afterward, the child becomes fully conscious. Pallid breath-holding spells (pallid infantile syncope) are less common and usually begin with sudden pain. The mechanism differs in that the child suddenly becomes pale and limp and loses consciousness. The pathophysiologic basis is increased vagal tone, which

causes an apparent asystole. The event ordinarily lasts only seconds to minutes, and the child awakens to full consciousness (also see Chapter 201, Temper Tantrums and Breath-Holding Spells).

#### Hyperventilation

Another benign cause of syncope, hyperventilation is frequent among adolescents, especially in the presence of anxiety. The hyperventilation results in the washing out of carbon dioxide, and the resulting hypocapnia causes reduced cerebral blood flow, dizziness, and syncope. Classically, hypoventilation is also associated with numbness and paresthesia of the hands and feet.

#### Psychiatric Syncope

A child with hysterical syncope is likely to be unusually calm. No autonomic effects such as change in heart rate or blood pressure are noted during the episodes, which tend to be recurrent and frequent and to occur in front of an audience. Recovery of consciousness is often prolonged, and no injury is usually sustained.

#### Cardiac Syncope

Syncope can result from a low cardiac output secondary to either a structural problem or a dysrhythmia, and the abnormal rhythm underlying the syncope may be either too slow or too fast.

#### Bradyarrhythmias

Sick sinus syndrome is extremely rare in a child with a normal heart and is usually seen after extensive surgery in the atria with the Senning and Mustard operations, performed for transposition of the great arteries. Patients who have undergone the Fontan procedure for a single ventricle may also be at risk secondary to atriotomies and dilated atria.

#### Atrioventricular Block

Very slow heart rates from atrioventricular (AV) block can lead to syncopal episodes termed *Stokes-Adams attacks*. Congenital AV block in the presence of a structurally normal heart is most commonly associated with a history of systemic lupus erythematosus in the mother. The structural heart disease, which is most commonly associated with congenital AV block and has an ongoing risk for acquired AV block, is corrected transposition of the great arteries. AV block is also occasionally acquired after cardiac surgery or Lyme disease.

#### Pacemaker Malfunction

In any child with a pacemaker, syncope should prompt immediate interrogation of the pacemaker for either a malfunction or inappropriate programming.

#### Tachyarrhythmias

##### Supraventricular Tachycardia

Most children with supraventricular tachycardia have a structurally normal heart, and in those children, palpitations and dizziness are more common symptoms

of supraventricular tachycardia than syncope. However, with a structural abnormality resulting in reduced hemodynamic reserve, as with a single ventricle, syncope may be a presenting feature. In patients with congenital heart defects, Wolff-Parkinson-White syndrome is most often seen in children with disorders of the AV fibrous valve annuli such as Ebstein disease and corrected transposition of the great arteries.

### **Ventricular Tachycardia**

Although ventricular tachycardia (VT) is rare in children, it can cause sudden death; early identification of underlying conditions that predispose to VT can be lifesaving. Prolonged QT syndrome is one such condition in which patients are at risk for sudden death secondary to a polymorphic VT termed *torsades de pointes*. The prolongation of the QT interval may be part of a congenital syndrome such as Romano-Ward syndrome, which is autosomal dominant, or Jervell and Lange-Nielsen syndrome, which is autosomal recessive and associated with congenital neural deafness. Both syndromes are caused by mutations in genes encoding cardiac ion channels. Prolonged QT also may be caused by electrolyte imbalances, such as hypokalemia or hypocalcemia, and by a variety of drugs, such as tricyclic antidepressants, certain macrolide antibiotics, and antiarrhythmic medications. VT can also occur in children as a complication of myocarditis or in adolescents with tetralogy of Fallot who have undergone surgical repair in infancy.

### **Structural Heart Disease**

An acute reduction in cardiac output can result in reduced cerebral perfusion and syncope. With certain heart conditions discussed later, patients may be able to maintain an adequate cardiac output at rest but experience syncopal episodes with exercise.

### **Aortic Stenosis**

An impediment to the forward flow of blood from marked left ventricular hypertrophy, stimulation of the ventricular mechanoreceptors resulting in systemic vasodilation, and subendocardial ischemia causing a ventricular arrhythmia are all mechanisms that may contribute to syncope in children with severe aortic stenosis.

### **Hypertrophic Cardiomyopathy**

Syncope with exercise may be an important presenting sign of hypertrophic cardiomyopathy. Most affected patients have no left ventricular obstruction at rest; however, with exercise, they can develop a dynamic gradient with an acute reduction in cardiac output. In addition, these patients may develop VT from subendocardial ischemia. The electrocardiogram is frequently abnormal, and an echocardiogram is diagnostic.

### **Tetralogy of Fallot**

Children with unrepaired tetralogy of Fallot may have syncopal episodes in association with hypercyanotic *tet* spells, often precipitated by crying, straining with a bowel movement, or awakening from sleep.

### **Pulmonary Hypertension**

With exertion, children with pulmonary hypertension may experience syncope from the inability to maintain transpulmonary flow.

### **Coronary Artery Abnormalities**

A patient with syncope who is demonstrated to have a coronary artery aberrant either in its origin or course should be presumed at risk for sudden death. Typically, syncope occurs with exercise. Acquired abnormalities of the coronary arteries include coronary artery aneurysms and stenosis caused by Kawasaki disease in early childhood. Cocaine use can cause acute coronary vasoconstriction and ventricular arrhythmias, with consequent syncope.

### **Neurologic Causes of Syncope**

#### **Seizures**

Typically, generalized seizures are preceded by a prodrome and include tonic-clonic activity with loss of consciousness and a period of confusion and lethargy after recovery. However, atypical seizures can occasionally be difficult to differentiate from the benign forms of syncope. Loss of consciousness occurring in the recumbent position is more likely to be from a seizure than from syncope, especially if the heart is normal. Pallor is seen more often in benign syncope, and flushing is more common with seizures. Bowel incontinence points toward a seizure.

#### **Migraine**

The primary care physician should always ask about migraine in a child who has a syncopal episode that does not fit the pattern of typical neurally mediated syncope, particularly if dizziness occurs in the sitting position and no other provoking factors can be elicited. A history of flashing lights, severe headache preceding the episode of syncope, and a family history of migraines usually help clinch the diagnosis.

#### **Head Trauma**

Brief loss of consciousness with head trauma is not uncommon and signals concussion.

#### **Metabolic Causes**

Hypoglycemia can cause syncope, most commonly in a child with diabetes on medication. Presyncopal symptoms such as weakness, a feeling of hunger, and confusion may be present, and the syncope is typically not brief. Dehydration and severe anemia also predispose to syncopal episodes.

## **EVALUATION**

### **History**

The history is the most important tool in the diagnosis of syncope. It should include a detailed inquiry into the exact circumstances surrounding the event, including the time of the day, presence of an upper respiratory infection, time since last meal, posture during syncope and time spent in this posture before syncope, presence of prodromal symptoms, duration of loss of consciousness, bystander testimony, and any headache or prolonged disorientation after syncope.

Inquiry should also include the circumstances precipitating the event. For example, with vasovagal syncope, the child often is standing in a warm, stuffy room and is hungry, tired, or frightened. The prodrome of a seizure may consist of an aura, whereas a cardiac event often occurs without warning or is induced by exercise. There may also be a history of palpitations just before the episode. The primary care physician should determine whether the child was completely unconscious or whether some degree of responsiveness was present, suggesting hysteria or malingering. A truly unconscious person will not respond if the eyelashes are lightly brushed; a hysterical person will respond, albeit often with just a mild flickering of the lids. Seizure-like movements are important; however, generalized tonic-clonic movements may be seen in any form of syncope. The duration of the episode should be estimated. In general, the conscious state is regained quickly in the case of vasovagal syncope (a few seconds to 1 or 2 minutes), whereas a seizure may last longer, and the postictal state may be characterized by prolonged confusion and fatigue.

A history of congenital heart disease, seizure disorder, or endocrine abnormality such as diabetes would obviously be important. Recurrent syncopal episodes are unusual and may require more extensive testing.

The family history may be helpful. Seizure disorders and cardiac disease leading to syncope (eg, Marfan syndrome, hypertrophic cardiomyopathy, prolonged QT syndrome) may be inherited in an autosomal-dominant fashion. Breath-holding spells can also have a familial pattern.

### Physical Examination

Examination of a patient with a history of syncope should begin with an assessment of the level of consciousness; a child who is not alert and oriented has not had a benign syncopal episode and needs immediate evaluation for potentially life-threatening causes. In most children who are fully alert after a syncopal episode, the findings on physical examination tend to be normal. The presence of a cardiac murmur may point to an obstructive lesion, such as aortic or pulmonic stenosis. Listening to the heart in both the supine and upright positions is important because a mild obstructive gradient in hypertrophic cardiomyopathy may become audible only when the patient is upright. The heart rate and blood pressure should also be obtained in both the supine and upright positions to ascertain the presence of orthostatic intolerance.

### Evaluation

#### Electrocardiogram

The only test indicated in most patients with a history typical for benign syncope is an electrocardiogram, which may reveal the presence of AV block or a dysrhythmia. Abnormally large left ventricular forces, especially with left ventricular strain, may be the only evidence of hypertrophic cardiomyopathy in a patient with normal findings on physical examination. The

corrected QT interval should be measured in all children with syncope or seizures as an initial screen for prolonged QT syndrome.

#### Holter and Event Monitor

A 24-hour electrocardiographic monitoring test is indicated only if a cardiac dysrhythmia is strongly suspected based on either prominent palpitations that occurred before the episode or the presence of cardiac surgical history that may predispose a child to abnormal rhythms. An event recorder is more practical because patients are able to keep the monitor for a month and use it at the time of their symptoms.

#### Echocardiogram

When a suspicion exists based either on history (eg, syncope with exercise) or examination of a structural cardiac lesion, an echocardiogram is indicated and can usually adequately demonstrate the origin and course of the coronary arteries.

#### Electrophysiologic Testing and Cardiac Catheterization

Electrophysiologic testing and cardiac catheterization must be considered for any patient who has had syncope during active exercise in whom a physical examination, electrocardiogram, and echocardiogram has failed to demonstrate an abnormality.

#### Tilt-table Testing

By creating an orthostatic stress, tilt-table testing can provoke symptoms in patients with NMS and orthostatic hypotension. Patients are placed supine on a table that has a foot board. The table is then tilted up between 60 and 80 degrees for 30 to 60 minutes. Patients are monitored closely for a syncopal episode. Some centers use low-dose intravenous isoproterenol infusions to increase the sensitivity of the test, which ranges from 30% to 80%, depending on the laboratory. The specificity of a negative test without isoproterenol ranges from 80% to 100%.

Although the utility of head-upright tilt-table testing in children is still controversial, it has become a means of provoking vasodepressor syncope in susceptible individuals after other more serious causes have been ruled out. Some indications for the use of this test include the following:

1. Three or more syncopal episodes during a 12-month period with no evidence of heart disease
2. Syncope during exertion in which heart disease has been ruled out after an exhaustive workup
3. Recurrent syncopal episodes thought to be hysterical in nature

### MANAGEMENT

The management of cardiac, neurologic, and psychiatric syncope depends on the cause. The management of NMS includes some of the following approaches.

#### Reassurance

The most important interventions for most patients who have NMS or orthostatic hypotension are reassurance and education regarding the cause of the

syncope and how to avoid aggravating factors (avoiding extreme heat and standing still for long periods). Patients should be instructed to sit down or lie down at the onset of any prodromal symptoms to avoid injury. Drinking fluids regularly and eating salty foods may be helpful in preventing episodes.

### Isometric Exercises

In a small randomized trial of adults, intense gripping of hands and tensing of the arms for 2 minutes at the onset of the tilt-induced symptoms raised systolic blood pressure. Syncope occurred in 37% of these patients compared with 89% of those who did not perform the maneuver. The value of *tilt training* is still controversial, but it may be helpful to some patients; they are instructed to stand with their backs against a wall, initially for short periods, and slowly increasing the duration to approximately 30 minutes per day.

### Volume Expansion

A reduced frequency of syncope in adolescents with neurocardiogenic syncope was reported after consuming 2 liters of water in the morning.

Fludrocortisone is a synthetic mineralocorticoid that causes salt retention and the expansion of the central blood volume. One randomized trial in adolescents showed similar results to atenolol, but no placebo was studied.

### Beta-blockers

Although beta-blockers have been used for many years as therapy for neurocardiogenic syncope, studies of their effectiveness have at best been equivocal.

### Investigational Agents

Midodrine is a direct  $\alpha_1$ -receptor agonist that has been shown to reduce episodes in adults with severely symptomatic neurocardiogenic syncope. Because serotonin may have a role in regulating the sympathetic nervous system activity, selective serotonin reuptake inhibitors have also been considered for treatment of NMS. In a trial in adults, paroxetine was shown to be superior to placebo.

### Cardiac Pacing

Currently, cardiac pacing has a very limited role in the management of syncope. In pediatrics, cardiac pacing has been used for children in whom asystole is the prominent symptom in recurrent syncope caused by vagal hypertonia, including some patients with deglutition syncope.

### WHEN TO REFER

- Patient history of cardiac disease
- Family history of sudden death, cardiac disease, or deafness
- Recurrent episodes
- Recumbent episode
- Exertional syncope
- Prolonged loss of consciousness
- Associated chest pain or palpitations
- Medications that can alter cardiac conduction

## Chapter 201

# TEMPER TANTRUMS AND BREATH-HOLDING SPELLS

Gregory E. Prazar, MD

### TEMPER TANTRUMS

Children exhibit temper tantrums almost inevitably during the second through fourth years of life. Therefore a temper tantrum is generally a *problem behavior* rather than a *behavioral problem*. Helping parents cope with temper tantrums involves providing anticipatory guidance, sharing information on developmental psychology, and offering strategies to deal with tantrums.

Temper tantrums usually become part of the child's emotional repertoire during the second and third years of life. Early signs of the negativism that is part of tantrums can be appreciated as early as 12 months of age. Some children continue to display occasional tantrums until the age of 5 or 6 years. Tantrums typically reappear in a slightly less intense form during adolescence, when independence once more becomes an issue for the developing adolescent.

Several aspects of the toddler's development seem to make tantrums almost inevitable. First, because the 1-year-old can walk and climb, the child begins to achieve physical mastery over the environment. This increased physical independence and an insatiable curiosity frequently place the child in dangerous situations that require parental intervention. Imposition of adult safety limits thwarts and frustrates the child, often precipitating tantrums. Second, the child's increased exploration of the environment immediately creates a conflict because the child must adapt to rules of an adult world. The child enters an environment of adult social values, in which people are expected to use the bathroom appropriately, verbalize dissatisfactions rather than *act* them out physically, sit quietly

while eating, and sometimes subjugate their own wants to those of others. This process is too much for the egocentric toddler to bear, and frustration is inevitable. Third, between the ages of 1 and 4 years, the toddler begins to develop an increased awareness of how the child is separate and different from the mother. The child experiences a conflict between desires for autonomy and desires to remain close to the mother. Frustration in dealing with these intense feelings frequently results in tantrums.

Tensions are created in “establishing ego boundaries as separate from those of parents,” as Brazelton states, and in coping with physical limitations placed on exploring an adult world. Adults frequently deal with their own tensions and frustrations by verbalizing their feelings; the toddler, however, lacks a sophisticated ability to verbalize. A toddler’s frustration with the adult world may be displayed in doing the exact opposite of what the adult requests, by saying “no, no” yet following through with the adult request (what Fraiberg refers to as the “cheerful no”), by dawdling, or by displaying physical behavior outright (eg, kicking, screaming, lying on the floor, hitting, throwing, biting).

Most parents would probably agree that intellectual appreciation of the cause of tantrums does not necessarily aid in coping with a screaming and inconsolable child. Reasons for parental frustration are understandable. Well-meaning relatives and friends (who have likely forgotten their experience as young parents) may propagate myths about tantrums, which intensify parental anxiety and confusion. Myths of causation suggest that children who display tantrums are underdisciplined or parented inadequately. Myths of management suggest that tantrums can be quelled by spanking, dousing with cold water, or threats.

## ANTICIPATORY GUIDANCE FOR TANTRUMS

The primary care physician should provide anticipatory guidance about temper tantrums. Such guidance may forestall events that precipitate tantrums and prevent future parental confusion in dealing with negative behaviors. The physician has many opportunities during the child’s first 2 years to provide behavioral counseling.

Beginning in infancy, parents should be provided with anticipatory guidance regarding opportunities for positive interactions with the child within daily routines and activities such as feeding, pretend play, and reading aloud. Howard and others have recommended “‘special time’ provided every day as an approach to formalizing time-in.”

At the 6-month well-child visit, the importance of parental time away from the infant can be emphasized. Parents who occasionally leave their infants and toddlers with responsible babysitters provide their children with the security that adults can leave and will come back; they also provide themselves with important mental health holidays from the rigors of parenting.

At the 9- or 12-month infant visit, environmental engineering should be discussed. Providing home safety (eg, safety plugs in outlets, safety latches on

drawers), removing valuables or breakables from the child’s reach, and ensuring a safe place for the child to play (playpen or enclosed area) are examples of such engineering. Therefore this visit not only may reduce chances for childhood accidents but also may forestall potential adult-toddler power struggles over environmental dangers.

The 15- or 18-month visit provides the physician another opportunity to offer the parent alternatives to negative interactions with the toddler. Afternoon naps (to allow for renewal of toddler and parental energy), the importance of praising cooperative toddler efforts, and the concept of limited decision making for the toddler (“Do you want to wear the green or blue shirt today?” versus “Which shirt do you want to wear today?”) represent issues that may help parents minimize hostile encounters with their toddler.

The approach here should encourage parents to describe how they think tantrums should be handled, and should not simply display the physician’s personal biases about child rearing. Several excellent books describing turbulent toddlerhood can be suggested to parents, including Brazelton’s *Toddlers and Parents*, Ilg and Ames’ *Child Behavior*, and Schmitt’s *Your Child’s Health*. Furthermore, general guidelines concerning tantrums can be given. Tantrums are best ignored unless, as Fraiberg states, “they encroach on rights of others or potentially endanger.” If safety is the issue, then either environmental engineering should take place or the child should be restricted to the child’s bedroom for 2 to 3 minutes (a kitchen timer is helpful to remind both parent and toddler of the time). If the child hits, bites, or throws in anger, then room restriction for 2 to 3 minutes should once again be suggested. Some behavioral psychologists suggest 1 minute of time out for each year of age (so a 5-year-old child would have a 5-minute time-out). Other behaviorists recommend that the time-out not be fixed. Because the goal is to help the child develop self-regulation, the time-out should end when the tantrum subsides. The child should receive a brief hug or be praised and then be allowed to resume previous activity.

Parents may be reluctant to use bedroom restriction because they worry either that the child will associate the bedroom with unpleasant experiences or that the child will not feel adequately remorseful if placed in a room full of toys. Parents should be reassured that room restriction does not cause bedroom fears. Similarly, goals of discipline are to teach rules and to help the child understand which behaviors are acceptable. Discipline does not need to be severe to be effective. The physician should emphasize to parents that once the tantrum is over, the slate is wiped clean and there is no holdover of judgment or anger, even if the child has acted out badly.

Time-outs are an effective method of dealing with temper tantrums. Time-ins represent a method to reward acceptable behavior. Specifically, when a toddler is playing quietly, the parent should pat the child on the shoulder, give a brief hug, or otherwise offer some form of nonverbal affection. Such attention from the parent simply but effectively indicates approval of the current behavior. Some behavioral psychologists

consider time-ins to be a more powerful method of encouraging acceptable behavior than time-outs.

Temper tantrums occur much more frequently in the presence of parents; they are much less common in the presence of alternative child care providers. Most experienced child care providers feel comfortable dealing with temper tantrums. If the child care provider expresses concern to a parent about a child's temper tantrums, then several questions should be considered. Does the child care provider have adequate training to deal with such a common behavior? Is this child care setting the most appropriate for the child (in terms of adult-child ratio, philosophy of discipline used by the provider, and realistic developmental expectations for the child's behavior in the child care setting)? Are the child's temper tantrums much more severe or frequent than those of the child's peers? These questions should be addressed with the child care provider. Subsequently, parents and the child care provider should formulate a plan for dealing with the tantrums that is followed consistently at home and at the child care location. If the parent and the child care provider cannot agree on such a plan, then the child's primary care physician should be consulted.

More specific guidelines for managing tantrums may be necessary in other individual situations. Parents should be encouraged by the physician to vent their feelings (to the physician) about tantrums and be reassured that they are doing the best job they can for their toddler.

## MANAGEMENT OF PROBLEM TANTRUMS

Although tantrums represent a stage of the normal developing toddler's personality, several factors may suggest that further professional intervention is advisable. An important aspect of management is obtaining a detailed history, including the circumstances in which tantrums take place, a specific description of the tantrums, and what happens following the tantrums. This is referred to as antecedent, behavior, and consequence or "A,B,C." Toddlers who display persistent negativism or tantrums may suffer from too restrictive parenting, may receive too little positive reinforcement and affection, or may have parents who place unreasonable behavioral expectations on them. One study of 3-year-olds defined severe temper tantrums as "episodes of shouting, banging, kicking, or screaming occurring 3 or more times a day or lasting more than 15 minutes." Approximately 50% of these children had behavior problems. Furthermore, such severe tantrums were associated with specific psychosocial issues, including maternal depression, use of corporal punishment, marital stress, and low maternal education.

Children who display tantrums regularly beyond 5 or 6 years of age may be displaying signs of depression or poor self-esteem, or they may be children who live in a family in which emotional problems exist. When temper tantrums regularly occur at school, academic problems should be suspected because peer pressure usually inhibits displays of tantrums.

Children exhibiting persistent tantrums along with other associated behaviors (eg, inability to

concentrate, stereotypical behaviors, unrealistic fears, inability to display affection) may have more significant underlying problems, such as attention-deficit disorder, oppositional defiant disorder, or autism spectrum disorder. Similarly, parents who verbalize persistent frustration with tantrums or an inability to cope with age-appropriate tantrums may need more comprehensive counseling than the primary care physician can provide.

Many parenting groups are available to help parents cope with negative behaviors. Programs such as Systematic Training for Effective Parenting (STEP) and Parent Effectiveness Training (PET) provide valuable community referral sources for families. If such services are not available, or if more sophisticated professional counseling is obviously warranted, then the family should be referred to a psychiatrically trained counselor.

Referral should be discussed as soon as the physician anticipates its necessity and should stress the involvement of both parents. The physician should maintain contact with the family about the problem after the referral has been made. Such ongoing contact may solidify the family's commitment to obtain and adhere with the counseling.

## BREATH-HOLDING SPELLS

Breath-holding spells cause particular anxiety for parents. Spells occur between ages 4 months and 5 years, with most occurring between 12 and 36 months of age. According to Menkes, approximately 5% of all children display breath-holding spells. A positive family history of breath-holding spells occurs in approximately 25% of cases.

Such spells are precipitated by anger, frustration, fear, or minor injury (often a very minor head injury) and are categorized as cyanotic or pallid. Both types of spells are unlikely to occur more often than once a day and are not associated with an increased predisposition to epilepsy (although brief seizure-like activity can occur as a terminating event in either form of spell).

Cyanotic breath-holding spells are precipitated more often by anger or frustration than by fear or injury. The child emits a short, loud cry, takes a deep breath, and holds it. Cyanosis occurs after approximately 30 seconds. Either the episode terminates at this point or the child becomes rigid or limp and loses consciousness (loss of consciousness occurs in approximately 50% of all children who have breath-holding spells). In rare situations, mild clonic movements of the extremities follow.

Pallid breath-holding spells are similar to cyanotic spells in most respects but are more often precipitated by fear or minor injury. The initial cry is brief or silent. The spell then proceeds as with a cyanotic spell. Toddlers who suffer from pallid spells are often from families that have a history of syncope, and, in fact, these toddlers have an increased chance (approximately 15%) of syncopal attacks as adults.

Both cyanotic and pallid breath-holding spells are caused by autonomic nervous system dysregulation. Cerebral anoxia is responsible for spells that terminate with loss of consciousness. Furthermore, both

forms of spells are involuntary and reflexive, despite spells often being precipitated when the child is angry or frustrated.

Children who display pallid breath-holding spells may, as adults, suffer from neurocardiogenic syncope, a form of vasovagal response to postural changes. Adults who suffer from neurocardiogenic syncope are more likely to faint at the sight of blood or when injured than are adults who do not have this disorder.

Because both forms of breath-holding spells potentially can terminate with seizure-like movements, differentiation between spells and epilepsy is important. The occurrence of a precipitating factor (eg, minor injury, being frustrated) before the onset of the spell indicates that the episode is a breath-holding spell. Patients who have epilepsy display cyanosis during or after the seizures, not before seizure onset. Furthermore, electroencephalograms performed on patients who suffer from breath-holding spells are normal when not holding their breath; patients who have epilepsy often have abnormal electroencephalograms during seizure-free periods.

## MANAGEMENT OF BREATH-HOLDING SPELLS

No effective medical therapy exists for breath-holding spells, although some toddlers who experience seizure-like activity along with spells are prescribed anticonvulsant therapy. However, the decision to use medication remains controversial among pediatric neurologists.

Iron deficiency anemia has been associated with breath-holding spells. A study involving 67 children who had breath-holding spells revealed that iron therapy reduced spells in the treatment group by 88%. These results suggest that iron may be important in the regulation of the autonomic nervous system.

Coping with breath-holding spells can be extremely difficult for parents. Spells that terminate with loss of consciousness or with seizure-like movements are obviously frightening. Convincing parents that no harm will come to their child is important. Nevertheless, parents of a breath holder will frequently avoid enforcing limits for fear of precipitating the child's anger and a subsequent attack. Such parents need repeated reassurance and encouragement to continue age-appropriate limits on their child's behavior. To do otherwise will create an overindulged child who subsequently may fear loss of parental love because limits have been rescinded.

When to refer a breath-holding patient to a neurologist or a psychiatrically trained professional may not be an easy decision for the physician. If parents request further consultation, then their wish certainly should be respected, even if the physician is confident that further evaluation is unnecessary. If parents indicate agreement with the physician that spells are of no consequence yet continue to withhold appropriate limit setting, then referral to a mental health professional should take place. The physician who is unsure of the diagnosis of breath-holding (especially in situations in which loss of consciousness or seizure-like activity occurs) should always refer the family to a pediatric

neurologist. Referral must not end the physician-parent communication concerning the spells: an ongoing dialogue may ensure adherence with the referral.

## SUMMARY

Temper tantrums and breath-holding spells usually represent benign forms of childhood behavior evolving from the child's preverbal attempts to express feelings of frustration and anger. Unfortunately, parents frequently have difficulty appreciating the benign course of such behaviors when they daily must face a screaming, inconsolable toddler who may even lose consciousness and then display seizure-like movements. Parents can best deal with negative behaviors when they are adequately prepared by the physician before such behaviors occur and when they are offered empathic guidance and positive reinforcement during regular office visits.

## Chapter 202 TICS

Robert A. King, MD

*Tics*, which are recurring, nonrhythmic, sudden, rapid, stereotyped, involuntary movements or vocalizations, may be classified as motor or vocal and as simple or complex. The most common *simple motor tics* are eye blinking, neck twisting, shoulder shrugging, and grimacing; the most common *simple vocal tics* are coughing, throat clearing, sniffing, and grunting. *Complex motor tics* include more sustained, orchestrated, or

seemingly purposeful gestures, such as touching, stomping on, or sniffing objects; jumping; sustained dystonic movements; copropraxia (obscene gestures); or echokinesis (automatic imitation of another person's movements). *Complex vocal tics* include sudden changes in volume or prosody; syllables, words, or stock phrases spoken out of context; palilalia (repeating one's own words); echolalia (repeating the words of others); and coprolalia (uttering obscenities).

Tic disorders are model neuropsychiatric conditions demonstrating the complex interplay of genetic, neurobiological, environmental, and psychosocial factors. That is, they have a constitutional, probably genetic basis; are influenced by perinatal risk and environmental factors; demonstrate sexual dimorphism; show a changing course over development; and, although neurobiologically determined, can be affected by psychosocial factors, such as stress and cognitive behavioral interventions.

## CLINICAL MANIFESTATIONS

The most common age at onset for tics is 6 or 7 years. The usual initial motor tics are blinking or facial grimacing, with subsequent rostral-caudal involvement. The most common initial vocal tics are sniffing, coughing, and throat clearing. Not surprisingly, these symptoms are often initially mistaken for allergies or otolaryngologic or respiratory symptoms; but with tics, the other characteristics of such disorders are absent. Characteristically, tics wax and wane in intensity and frequency, with a tic disappearing only to have new ones take its place. Stress or excitement often exacerbates the tics.

Although children are generally unaware of their tics, premonitory urges are often reported in more severe cases or in older children. Tics are often transiently suppressible with effort, usually resulting in an increased urge to perform the tic. Many patients describe their tics as neither fully voluntary nor involuntary; some experience the effort to suppress tics in social situations to be as burdensome as are the tics themselves.

## INCIDENCE

It once was believed that *Tourette syndrome* (TS) was rare, persistent, severe, and disabling. It is now clear that tic disorders, including TS, exist on a clinical spectrum from transient, isolated, inconsequential tics to more persistent multiple motor and vocal tics that interfere with daily functioning. Isolated and transitory tics are common (occurring in as many as 24% of first- and second-graders) and of minimal consequence. Depending on ascertainment methods, childhood prevalence of TS is thought to be 2 to 185 per 10,000—much higher than previously believed, with many milder, uncomplicated cases not coming to clinical attention. Boys are affected more than girls, by a ratio as high as 9:1 to 14:1 in TS.

## ETIOLOGY

The cause of tics is unknown, but neurobiologic and behavioral research shows the boundaries between psychiatric and neurologic domains to be poorly

defined and increasingly obsolete. Most of this research has been on TS rather than on milder forms of tic disorder. Areas of interest have been basal ganglia and cortico-striatal-thalamo-cortical circuitry, genetics, and immunology. A multifactorial etiology for TS, with a convergence of genetic vulnerability, environmental and perinatal risk factors, and disturbances in the prefrontal cortex and basal ganglia, has been proposed. Several factors have been shown to be associated with tics and may give clues to their cause.

### Developmental Stage

Tics usually have their onset between 5 and 10 years of age, most commonly at 6 or 7 years. Although fluctuating in intensity from hour to hour and day to day, tics are usually at their most severe at around 10 to 13 years of age. Approximately 70% to 80% of the time, tics spontaneously diminish in severity during the course of adolescence and disappear or become minimal by young adulthood. Comorbid conditions, however, such as obsessive compulsive disorder (OCD), attention-deficit/hyperactivity disorder (ADHD), and anxiety disorder, may persist. The factors associated with spontaneous improvement or remission remain unclear and are important areas of research.

### Sex

Transient tics as well as chronic tic disorders are more common in boys than in girls. Androgens are implicated for multiple reasons—postnatal exposure to androgens may elicit TS; antiandrogen therapy may improve tics; and androgen-dependent alterations in prenatal brain development may be associated with TS.

### Prenatal, Perinatal, and Postnatal Factors

Factors that have been associated with tic severity also have been associated with other neuropsychiatric symptoms and disorders, such as hyperactivity; in particular, prenatal factors, such as maternal smoking, vomiting, psychosocial stress, drug use, fetal nutrition, and androgen exposure, and perinatal factors, such as low birth weight.

Experts have proposed that, in some cases, the acute onset of tics represents a form of pediatric autoimmune neuropsychiatric disorder associated with *Streptococcus* (PANDAS). This controversial hypothesis posits that group A  $\alpha$ -hemolytic streptococcal infection can cause an autoimmune reaction that attacks the basal ganglia, resulting in tics, OCD, or both. Despite much ongoing research, this hypothesized autoimmune condition remains unproven. In the absence of a biological marker, distinguishing which cases might represent true PANDAS as opposed to the non-specific coincidental occurrences of 2 common childhood conditions (streptococcal pharyngitis and tics or OCD) is difficult, at least at the onset. In one large study, children subsequently diagnosed with de novo tic disorder were found to have a greatly increased rate of streptococcal infections in the months before diagnosis.

Pending further research to clarify this matter, some primary care physicians have chosen to obtain

throat cultures from children with sudden onset or exacerbations of tics and from children with tics or OCD who have pharyngitis or who are exposed to *Streptococcus*. Children with positive throat cultures should receive appropriate antibiotic treatment. There is no established role for repeat posttreatment cultures to prevent streptococcal carrier states, nor does the use of prophylactic antibiotic treatment have any firm basis in evidence. Plasmapheresis or intravenous immunoglobulin therapy are only suitable in intractable cases as part of an approved investigational protocol.

### Psychological Factors

Anxiety, stress, and excitement can all exacerbate tics. Little is known about the psychological status of most children in the general population who have tics, because they are rarely seen in clinics. However, evidence exists for increased autonomic lability in individuals with TS, and children who have anxiety disorders are overrepresented in clinical samples.

### Psychiatric Disorders

Population and clinical studies of tics point to a strong relationship, most marked in TS, between tics and ADHD.

A relationship also exists between tics (especially in TS) and OCD, with symptoms (eg, premonitory urges, intrusive thoughts, compulsive actions), putative anatomic locus (cortical, striatal, or thalamic circuits), hypothesized pathophysiologic features (rogue reverberating microcircuits), and family pedigrees all showing elements in common.

Tics should never be assumed to indicate another psychiatric disorder or psychological problem unless they are associated with other signs or symptoms that affect other areas of function beyond the motor system. Although tics can be controlled to some degree in public situations (eg, school or a physician's office), an affected child should not be expected to control them most of the time. Such control requires considerable mental energy and effort and usually cannot be sustained for long. As soon as the child relaxes, is distracted, or lets up concentration, the tics will reappear.

### Genetic Factors

Many cases of tics, especially TS, appear to be genetic in origin. Mild and transient cases of tic disorder may coexist in the same pedigree as cases of TS, suggesting that protective and risk factors also exist. Even with monozygotic twins, the concordance rate is only 77%, which suggests that environmental factors (eg, low birth weight) also play a role. Although specific genes have been identified in a handful of pedigrees, the condition may well be heterogeneous (ie, different specific genes may be responsible in different pedigrees) and perhaps polygenic (ie, reflecting the interaction of multiple vulnerability loci). Penetrance increases if OCD is accepted as an alternative expression of the gene.

### Drugs

Amphetamine and other dopaminergic drugs induce stereotypies in rats and occasionally produce or

exacerbate tics in children. Cocaine, other stimulants, sympathomimetics, caffeine, serotonin uptake inhibitors and other antidepressants, and anabolic steroids may also produce or exacerbate tics.

## DIFFERENTIAL DIAGNOSIS

Tics are usually distinguishable from other neurologic disorders by their stereotyped nature, variability over time, transient suppressibility, accompanying premonitory urges, and lack of other neurologic symptoms. The differential diagnosis includes dystonia, myoclonus, chorea, seizures, athetosis, and stereotypies.

Tics are distinguishable from *chorea* (with which they are often confused) by their centripetal location, repetitive form, normal muscle tone, and lack of postural impersistence; and from most other neurologically based abnormal movements by their rapidity and normal muscle tone. Even so, tics rarely reflect or portend a neurologic disorder. Such tics are likely to be much more persistent and accompanied by signs of the disorder that causes them.

A more difficult diagnostic quandary in young children is distinguishing true tics from stereotypies or self-stimulating behaviors, such as rocking, head banging, flapping, or spinning. Tics are characterized by a later onset, lower complexity, fluctuating intensity and locus, and their intrusive, bothersome, disruptive, and involuntary nature. In contrast, stereotypies are most often bothersome to parents but not to the child, who may find them pleasurable and resist adult attempts to interrupt them. Self-stimulating movements mostly occur at times of boredom or excitement, but they rarely disrupt coordinated movements, and they persist without much change in form or anatomical location. Although stereotypies are often associated in many physicians' minds with intellectual disability or autism spectrum disorders, in fact they can also occur in children who are otherwise developmentally normal (see Chapter 192, Self-stimulating Behaviors).

The most recent edition of the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* distinguishes 3 arbitrary subtypes of tic disorder: *provisional* (present for less than 1 year since first tic onset); *persistent (chronic)* (motor or vocal tics, but not both, that have persisted longer than 1 year since first tic onset); and *Tourette disorder*, also known as Tourette syndrome (multiple motor and at least one vocal tic, not necessarily concurrently, persisting at least 1 year from first tic onset). Whether these 3 classifications reflect varying severity of the same disorder is unknown. Most recent research has been restricted to TS but suggests that these subtypes are probably related.

## COMORBID DISORDERS

Persistent tics, even mild ones, seem to be associated with an increased risk of comorbid ADHD, which predates the tics or any accompanying OCD. This association is not simply the result of the bias toward comorbidity in clinical sample populations because it is also found in community sample populations. In

addition, many youngsters with TS whose concentration is basically good can become distracted and lose focus when their tics are in a period of exacerbation, presumably because of the tics themselves and the impingement of tic urges and efforts to suppress them.

Individuals with TS are also at risk for other anxiety disorders, depression, fine-motor difficulties, and uneven cognitive profile (performance IQ scores lower than verbal IQ scores). ADHD is common (present in 50% of patients with TS), and children with combined ADHD and tics have the greatest social and academic difficulties. ADHD severity is a better predictor of poor adjustment than tic severity. Although the presence of ADHD with tics increases the likelihood of disruptive behavior and learning problems, chronic tics are often associated with learning impairment independent of ADHD. Investigations of both community and clinical sample populations confirm that the presence of ADHD predicts greater disability than that associated with tic disorders alone.

OCD is found in up to 50% of patients with TS, with compulsions and obsessions most commonly involving symmetry, evening up, *just right* phenomena, sex, and aggression.

## TREATMENT

Most tics in children are mild and short lived and require no treatment. A careful clinical evaluation is needed to assess not only the current phenomenology, history, and effect of the tics, but also the presence of other symptoms (anxiety, impulsivity, inattention) or adaptive difficulties in the overall context of the child's social, family, and school life.

Once a tic has persisted for several months, treatment may be considered, but only if the tic is conspicuous, disabling, or distressing to the child. No treatment for tics can be said to be simple, entirely effective, or free from side effects. Treatments shown to have some limited efficacy are discussed in the following sections.

### Behavioral Methods

Although a variety of behavioral techniques (eg, relaxation, massed practice) have been tried for tic disorders, only comprehensive behavioral intervention for tics (CBIT) seems to have good empirical support. As the name conveys, CBIT is an effective evidenced-based behavioral approach to tics that combines habit reversal and contingency management techniques. Habit-reversal therapy is best carried out by a physician who is experienced in the technique and who is accustomed to working with children. Cognitive behavioral interventions may also be helpful for youngsters whose tic disorder is accompanied by disruptive behavior and explosive outbursts.

### Anxiety-Reducing and Supportive Procedures

Relaxation training and biofeedback are not of proven value in treating tics. Psychotherapy (specifically focused on stressful interpersonal difficulties), work with parents, and other means of addressing environmental stresses may be helpful, not because stress causes tics,

but rather because stress and high expressed emotion can exacerbate tics. These procedures should not be considered specific; rather, they are ancillary and holistic in meeting therapeutic objectives.

Many youngsters with tic disorders have difficulties at school, either from comorbid ADHD or an uneven neuropsychological profile, or difficulties with peer stigmatization. Close collaboration with school staff to ensure appropriate educational programming and accommodations is important.

### Acceptance

In most cases, the best management is explaining to parents, teachers, and peers that the tics are a physical disability, that the child cannot help them, and that acceptance of both child and tics is the kindest, safest, and simplest way to deal with them. Criticizing and belittling the child are likely to make tics worse and prolong their course. Peer problems can be a major difficulty for children with tics and TS, and collaboration with school staff to reduce peer teasing and stigmatization is a major therapeutic task. Helping to support and build upon the child's strengths is an important component in bolstering and protecting the child's self-esteem. In emphasizing that children cannot help their tics, the physician and parents should avoid the pitfall of concluding that the child cannot help other problematic behaviors related to impulsivity, for which consistent structure, expectations, and consequences are desirable and beneficial.

### Pharmacotherapy

Only physicians thoroughly familiar with the drugs indicated and experienced in their use in children with tics should undertake pharmacotherapy. The first consideration is deciding which symptom to target: the tics themselves or 1 of the common comorbid symptoms or conditions, such as OCD or ADHD, which are often a greater source of impairment.

### Pharmacotherapy for Tics

Various medications are effective in partially suppressing tics, but they are not curative in terms of affecting the underlying course or prognosis of tics. Furthermore, because of frequent side effects (especially sedation), medication should be administered only if the tics are significantly bothersome, disruptive, stigmatizing, or painful. The first mandate is to do no harm. In the case of tics, this approach means starting with low doses, titrating the dose upward only gradually, and avoiding sedation, cognitive blunting, or other distressing side effects (eg, acute dystonic reactions) that may be more burdensome than the tics themselves. Setting realistic goals in terms of reducing tics to tolerable levels is important; attempts to suppress tics completely often result in overmedication. Discontinuing anti-tic medications should be done gradually, because even when medications seem ineffective, abrupt discontinuation may produce bothersome acute rebound or withdrawal-related exacerbation of tics that may persist for several weeks.

Many physicians' first choice of anti-tic medication, especially in children with comorbid ADHD, is 1 of the

$\alpha$ -adrenergic agonists, clonidine or guanfacine. Although these agents are less potent and are effective in fewer patients with severe tics than the neuroleptics, they tend to have fewer and less severe side effects, with the principal dose-related side effects being sedation and hypotension. They are, however, potentially fatal in overdoses. Guanfacine, when available, is the preferred first choice because it is longer acting and less sedating than clonidine, and it seems to be more effective for attentional problems. Although sustained-release forms of both clonidine and guanfacine are available, it is usually preferable with younger children to begin on smaller doses of the short-acting form, titrating slowly with only small-dose increments to avoid sedation.

If the  $\alpha$ -adrenergic agents are not effective or if the tics are severe, then the next line of agents is the dopamine-blocking neuroleptics, now known as antipsychotic drugs. These agents seem to be effective because tics, whatever their cause, are executed through the basal ganglia, with an apparent relative overactivity in the dopaminergic nigrostriatal systems that inhibits cholinergic basal ganglia systems. However, the neurochemistry of tic disorder is complex and probably involves several neurotransmitter systems; therefore, inferring underlying deficits from the observed therapeutic effectiveness of various agents is difficult.

Of the traditional *typical* so-called *high-potency* (ie, nonatropinic) neuroleptics, haloperidol, pimozide, or fluphenazine have been shown to be effective, but have largely been replaced in clinical practice by the newer, so-called atypical antipsychotics. As with several of the other typical neuroleptics (eg, ziprasidone), caution must be exercised with pimozide in terms of cardiotoxicity and drug interactions, especially with drugs such as erythromycin that are metabolized through the cytochrome P450 3A4 isoenzyme system, because fatal drug interactions can result. Monitoring the QTc interval at baseline and with dose increases is prudent in patients receiving pimozide or ziprasidone. Even at relatively low doses, neuroleptics may produce acute dystonic reactions, sedation, cognitive blunting, medication-induced separation anxiety, parkinsonism, akathisia (restless legs), and, in the longer term, withdrawal or tardive dyskinesias, 1 rare type of which may be a worsening of tics caused by presumed dopamine-2 receptor hypersensitivity. If moderate doses are not effective, then higher doses are not likely to be either, and higher doses almost always increase the risk of side effects and make weaning the patient from the drug difficult without rebound exacerbation.

Although tardive dyskinesias are rare in children who receive modest doses of neuroleptics for tics, the traditional, or typical, antipsychotics are now being replaced by the newer so-called atypical antipsychotics, which seem to have a lower risk of tardive dyskinesia. However, atypical neuroleptics have the same other adverse effects as typical neuroleptics, including acute dystonic or extrapyramidal reactions, sedation, or dysphoria. In addition, risperidone and olanzapine may cause hyperphagia and weight gain, with potentially serious metabolic consequences. Clinical trials

have demonstrated the efficacy of risperidone, olanzapine, and ziprasidone for tics, but the lack of efficacy of the paradigmatic atypical neuroleptic clozapine indicates that not all atypical neuroleptics are equally effective.

When neither  $\alpha$ -adrenergic agents nor neuroleptics are effective, a variety of second-line drugs or augmentation strategies may be tried with caution. Although some neurologists use clonazepam to manage tic disorders, it should be used only in rare instances in children. Like the other benzodiazepines, clonazepam can cause cognitive blunting, sedation, irritability, and disinhibition, and its use can lead to dependence and withdrawal symptoms.

Tics should be treated pharmacotherapeutically only if significantly impairing, and only by a physician skilled in the use of the drugs concerned—ordinarily a child or adolescent psychiatrist or a pediatric neurologist. Such treatment should be carefully considered and discussed with parents, closely monitored, and undertaken only with knowledge and consideration of the risks and disadvantages involved.

### **Pharmacotherapy for Attention-Deficit/Hyperactivity Disorder, Obsessive-Compulsive Disorder, Anxiety, and Depression**

Pharmacotherapy for impairing comorbid ADHD, OCD, anxiety, or depression may be indicated in children with tic disorder, bearing in mind some considerations specific to tic disorder. Because ADHD is often more disabling than the child's tics, a cautious trial of a stimulant may be necessary, beginning with very low doses and increasing only gradually to avoid exacerbating tics. Alternatives to the stimulants are the  $\alpha$ -adrenergic agents (clonidine or guanfacine), atomoxetine, or 1 of the second-line drugs such as the older tricyclic antidepressants (with appropriate electrocardiogram monitoring). Most children with tics and ADHD are able to tolerate methylphenidate, and the combination of methylphenidate and clonidine seems more effective than either agent alone.

The SSRIs seem to be effective in children with OCD and tics, although evidence suggests that monotherapy with the SSRIs is less effective in the presence of tics. In such cases, augmentation with a low dose of a neuroleptic often boosts the treatment response. In rare cases, SSRIs can exacerbate or even precipitate tics, akathisia, or other movement abnormalities, or can increase suicidal thinking.

## **MANAGEMENT**

Most tics last only a few weeks, although they may flit from 1 muscle group to another or change their form at irregular intervals. Even the chronic tics of TS are likely to disappear in later adolescence, with tic severity peaking at age 10 to 12 or so. Although most tics improve by late adolescence, OCD or ADHD symptoms may persist. Because the prevalence of tics drops sharply after age 13, tics that persist into later adolescence are more likely to become chronic. Tic severity in adulthood is inversely proportional to caudate

volume in childhood and to childhood performance on a dominant hand fine-motor skill test.

Children with tics and especially TS can experience related problems of self-image when adult criticism and peer rejection result. Occasionally, severe complex motor tics result in injury or self-mutilation. Finally, OCD may develop during adolescence or late in TS and can be a persistent source of distress despite the improvement in tic severity with age.

Data from community surveys suggest that tic disorders, including TS, exist on a spectrum from transient to persistent multiple motor and vocal tics that in more severe forms interfere with daily living. The presence of isolated and transitory tics is common and seems to be of minimal consequence. On the other hand, persistent tics, even mild ones, seem to be associated with increased prevalence of ADHD, OCD, disruptive behavior, learning problems (although not necessarily a formal learning disability), and vulnerability to anxiety and depression.

Children should be referred to a specialist if the differential diagnosis is unclear, if a psychiatric disorder is present or is a possibility, if psychiatric drugs or treatments are needed, or if an expert opinion is required.

Referral is likely to be influenced as much by associated problems as by the tics themselves. The emphasis of treatment may thus focus less on tics per se than in mapping other areas of dysfunction.

Criteria for referring children to a specialist with expertise in the diagnosis and management of tics are the following: presence of tics associated with additional evidence of psychiatric disorder, such as ADHD, generalized anxiety, or OCD; presence of chronic or recurrent tics that seem to have a clear relationship to stress, particularly if a reason exists to think that psychosocial interventions may be helpful; presence of chronic, disabling, or discomforting tics for which differential diagnosis or treatment is needed; when the primary physician knows little about tics and wants an expert opinion; or when psychoactive drugs such as antipsychotics (neuroleptics) or  $\alpha$ -adrenergic agents may be indicated, because psychiatrists and developmental-behavioral pediatricians routinely use these medications and are well informed about risks, side effects, dose levels, and newer drugs.

Such referral may be only for consultation, not necessarily for continued management. In general, the preferred mental health specialist is a well-trained child or adolescent psychiatrist, or developmental-behavioral pediatrician—one who has a broad biopsychosocial perspective, including a good grasp of neuropsychiatry and pharmacotherapy but who will not overprescribe and who has a capacity to work closely with behavioral psychologists. This kind of specialist should also be alert to the possibilities of the rare neurologically induced tics and willing to order any appropriate neuroimaging studies and neurologic consultations. When the tic is disabling and no further diagnostic workup is required, or when pharmacotherapy is not an option or is already in place but further relief is necessary, referral

should be made to a child psychologist experienced in behavioral types of treatment. Consultation from a clinical psychologist is also useful if a child is having difficulties at school that are not simply caused by teasing or the distraction of tics or tic urges. Many children with tic disorders benefit from close collaboration with their school, which may include making the teacher aware of the tics and providing accommodations such as the ability to step out of class briefly when tics especially intrusive or bothersome.

### WHEN TO REFER

- Differential diagnosis is unclear
- A psychiatric disorder is present or a possibility
- Psychiatric drugs or treatments are needed
- For expert opinion

### WHEN TO ADMIT

- Never in the first instance (for tics alone)
- Occasionally, for complex assessments to initiate treatments or to taper a child from high doses of multiple medications

## Chapter 203

# TORTICOLLIS

Philip O. Ozuah, MD, PhD; Catherine C. Skae, MD

The word *torticollis* originates from 2 Latin words: *tortus*, which means *twisted*, and *collum*, meaning *neck*. The classic clinical picture of torticollis is that of the head tilted to one side and rotated in such a way that the chin and face point to the contralateral side. Torticollis can be broadly classified as either *congenital* or *acquired torticollis*. Facial asymmetry is often observed in congenital torticollis but not in acquired torticollis. This finding can thus be useful in clinically distinguishing between the 2 forms.

## CLINICAL MANIFESTATIONS

### Congenital Torticollis

Muscular torticollis is by far the most common form of congenital torticollis, and it occurs clinically in the first 8 weeks of life. It is frequently not obvious at birth but begins to become apparent at approximately 2 weeks of age.

Several theories have been proposed to explain the cause of this disorder. One theory suggests that stretching of the neck during a difficult delivery results in rupture and hemorrhage within the sternocleidomastoid muscle (SCM). Subsequent muscle ischemia results from increased pressure from the blood trapped within the fascial compartment, producing progressive muscle fibrosis and contracture, with eventual clinical torticollis. Support for this theory comes from the fact that about 40% of patients with congenital torticollis have had a difficult birth, including forceps delivery and breech presentation. However, congenital torticollis has also been reported in children after uncomplicated births. In addition, specimens of SCM in patients with torticollis have sometimes shown no evidence of trauma or hemorrhage. Another theory, therefore, is that torticollis results from an intrauterine position that occludes venous drainage from the SCM, leading to vascular congestion, ischemia, muscle damage, and fibrosis. This theory is supported in that 75% of congenital muscular torticollis cases are right sided because of intrauterine, left occiput–anterior positioning, and about 20% of patients who have congenital torticollis also have other musculoskeletal anomalies, including congenital hip dysplasias, talipes equinovarus, and metatarsus adductus.

Congenital torticollis can produce some variation. Most commonly, a sternomastoid tumor or pseudotumor is palpable as a characteristically nontender, soft, and mobile mass in or next to the inferior aspect of the SCM. The mass enlarges in the first few weeks of life, reaching its maximal size at 1 month of age. Thereafter, it begins to shrink until it disappears by 4 to 6 months. The mass then regresses and is replaced by a fibrous band, leading to contracture, which prevents normal growth and normal range of motion of the neck, and facial asymmetry results from the uneven growth

forces. A second form of congenital torticollis involves thickening and tightness of the SCM itself. Finally, *congenital postural torticollis* occurs without the presence of a palpable mass or tightness of the SCM.

The twisted position of the neck can lead to positional plagiocephaly. Skull flattening on the contralateral side may result from sleeping supine. Thus, plagiocephaly can be the presenting sign of mild torticollis.

### Acquired Torticollis

As with congenital torticollis, most cases of torticollis encountered in older children are primarily muscular in origin. Cervical muscle or ligament injury arising from trauma can cause a head tilt and unilateral neck tenderness, a condition that can also occur on awakening, presumably as a result of awkward positioning of the neck during sleep.

*Benign paroxysmal torticollis* is a disease of infancy with an unknown cause, although a familial pattern has been described. Manifestations of the condition begin in the first year of life with recurrent episodes of head tilt that may be associated with emesis, pallor, agitation, ataxia, malaise, and behavioral changes. Attacks may last from several hours to several days. Spontaneous and complete remission usually occurs by 5 years of age. Some patients, however, go on to develop migraines or benign paroxysmal vertigo.

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis of torticollis is listed in Box 203-1.

### Congenital Torticollis

Several congenital cervical spine anomalies can occur in conjunction with torticollis. Most of these anomalies can be diagnosed by radiographic studies of the cervical spine. *Pterygium colli*, a congenital web of the skin of the neck extending from the acromial process to the mastoid, can be restrictive and result in torticollis. *Congenital remnant cysts* within the body of the SCM are a less common cause of torticollis. Unilateral absence of one SCM results in unopposed action of the other muscle and produces a contralateral torticollis.

### Acquired Torticollis

Conditions that need to be considered in the differential diagnosis of acquired torticollis include cervical spine subluxations, infections of the head and neck (Grisel syndrome), neurologic disorders, and neoplasia. Laxity of the transverse cervical ligaments results in atlantoaxial instability in up to 15% of patients with Down syndrome. Most of these children are asymptomatic, but subluxation of the cervical spine, most commonly a rotational atlantoaxial subluxation, may occur after trauma. Nontraumatic subluxations of the atlantoaxial spine may arise as a result of head and neck infections or juvenile idiopathic arthritis (JIA). Torticollis may be the presenting finding in either the systemic onset or polyarticular forms of JIA, but this is rare. The current theory is that inflammatory reactions around the spine produce hyperemia and edema, which, in turn, lead to laxity of the supporting

**BOX 203-1 Differential Diagnosis of Torticollis****CONGENITAL**

- Muscular torticollis
- Postural torticollis
- Cervical spine anomalies
- Hemivertebra
- Atlantooccipital fusion
- Klippel-Feil syndrome
- Sprengel deformity
- Pterygium colli (webbed neck)
- Sternocleidomastoid cysts
- Cystic hygroma
- Bronchial cleft cyst
- Unilateral absence of sternocleidomastoid
- Occipital condylar dysplasia

**ACQUIRED**

- Muscular
  - Cervical muscle injury
    - Traumatic
    - Awkward positioning during sleep
- Vertebral
  - Atlantoaxial subluxation
    - Laxity of the transverse cervical ligaments results in atlantoaxial instability in up to 15% of patients with Down syndrome.
  - C2–C3 subluxation
  - Rotary subluxation
  - Cervical fractures
  - Cervical vertebral osteomyelitis
  - Juvenile idiopathic arthritis (JIA)
    - Torticollis may rarely be the presenting finding in either systemic onset or polyarticular JIA.
    - Inflammatory reactions around the spine produce hyperemia and edema, which lead to laxity of the supporting ligaments and a predisposition to spontaneous subluxations and torticollis.
  - Acute cervical disk calcification caused by trauma or respiratory infection
- Infectious
  - Infection of the head and neck (Grisel syndrome)
  - Upper respiratory infection
  - Retropharyngeal abscess
  - Cervical lymphadenitis
  - Cervical vertebral osteomyelitis
  - Dental infection
- Neurologic
  - Ocular torticollis with
    - Strabismus
    - Nystagmus
  - Refractive errors
  - Paralysis of extraocular muscles
  - Spasmus nutans (nystagmus, head nodding, and torticollis)
    - No known cause.
    - Signs and symptoms usually develop within the first 2 years of life.
    - May persist for months to years, but the course is often benign and self-limited.
    - But if accompanied by ataxia, suspect a cerebellar tumor.
  - Dystonic torticollis
    - May follow the administration of phenothiazines, carbamazepine, or phenytoin.
    - Presence of other extrapyramidal signs can confirm a dystonic reaction.
  - Syringomyelia
  - Epidural hematoma
  - Labyrinthine torticollis
  - Brachial plexus palsy
  - Arnold-Chiari malformation
  - Accessory nerve palsy
  - Acute disseminated encephalomyelitis
  - Wilson disease
- Neoplastic
  - Cervical cord tumor
  - Posterior fossa tumor
  - Soft tissue tumor
  - Langerhans cell histiocytosis (histiocytosis X)
  - Infantile desmoid fibromatosis
- Other
  - Benign paroxysmal torticollis
  - Psychogenic torticollis
  - Sandifer syndrome
    - An abnormal posturing that includes torticollis and opisthotonos
    - Believed to be a protective mechanism adopted by some patients with gastroesophageal reflux, esophagitis, or hiatal hernia
  - Dermatogenic torticollis
    - A painful, stiff neck resulting from extensive local skin lesions
  - Spurious torticollis
    - Stiffness of the neck from dental malformations or caries

ligaments and a predisposition to spontaneous subluxations and torticollis.

Torticollis may also arise from acute cervical disk calcification caused by trauma or from an upper respiratory infection. *Ocular torticollis* may be caused by

paralysis of the extraocular muscles, strabismus, nystagmus, and refractive errors. *Spasmus nutans*, also known as *nodding spasms* or *salaam spasms*, includes a triad of acquired nystagmus, head nodding, and torticollis, without a known cause. Signs and symptoms

usually develop within the first 2 years of life and may persist for months to years. However, the clinical course often is benign and self-limited. A *dystonic torticollis* may follow the administration of several drugs, including phenothiazines, carbamazepine, and phenytoin. The presence of other extrapyramidal signs can often be used to distinguish patients who have dystonic reactions.

Neoplasms associated with torticollis include cervical cord tumors and cerebellar tumors. Posterior fossa masses may manifest similarly to spasmus nutans with nystagmus, head nodding, and torticollis. For patients with cerebellar tumors, however, ataxia is often a cardinal feature. *Sandifer syndrome* is an abnormal posturing that includes torticollis and opisthotonos. This syndrome is believed to be a protective mechanism adopted by some patients with one of several conditions, including gastroesophageal reflux, esophagitis, or hiatal hernia. *Dermatogenic torticollis* is a painful, stiff neck that results from extensive local skin lesions. Stiffness of the neck resulting from dental malformations and caries is called *spurious torticollis*.

## EVALUATION

### History

The first step in determining the cause of torticollis should be to obtain a thorough and detailed history. Particular attention should be given to duration of symptoms, variation in severity of symptoms at different times of day (morning stiffness), previous trauma, presence of fever, and other systemic manifestations, including other musculoskeletal system symptoms. In younger patients, the birth history is essential.

### Physical Examination

Physical examination should not be limited to the head and neck areas but should include all organ systems. Findings such as craniofacial asymmetry suggest a congenital torticollis of long duration. The presence of webs or cysts in the neck should raise the suspicion of pterygium colli or remnant cysts. Patients with acquired torticollis as a result of trauma often have a tender SCM. Point tenderness over the cervical spine may suggest an underlying fracture or subluxation. Cervical vertebral osteomyelitis should be suspected in patients who have point tenderness in association with an unexplained fever. A thorough examination of the musculoskeletal system is necessary to examine muscle tone, muscle strength, hip positions, and the alignment of the lower extremities and feet. All vertebrae must be examined, with attention paid to the presence of sacral dimples. Examination of peripheral joints should be done to assess for evidence of arthritis in the forms of joint swellings or limitations of movement in association with pain, warmth, or redness. A thorough neurologic exam must be completed, checking cranial nerves and including vision, sensation, reflexes, fine and gross motor skills, and cerebellar testing.

### Laboratory Evaluation

The presence of peripheral leukocytosis and increased sedimentation rate can be helpful adjuncts

in diagnosing torticollis caused by infection or inflammation.

### Imaging Studies

Imaging of the cervical spine should be obtained in all neonates with torticollis and in older children who have findings that suggest vertebral involvement or who have persistent torticollis. Ultrasound is the imaging modality of choice for initial evaluation. Patients with neurologic deficits should undergo prompt computed tomography scanning or magnetic resonance imaging of the head and neck.

## MANAGEMENT

Congenital muscular torticollis responds well to prompt conservative treatment during the first year of life. Medical management includes passive and active stretching of the neck. *Gentle (passive) stretching* can be performed daily by the parents of the child or by a physical therapist. *Active stretching* is achieved by manipulating the infant's environment in such a way that objects of interest are located on the opposite side of the room from the torticollis, inducing the infant to turn the neck in the desired direction.

Surgical correction is essential if the deformity persists beyond the first year of life, if range of motion is restricted more than 30%, or if residual craniofacial deformity exists. Craniofacial asymmetry is best reversed at an early age when the child's growth potential is at its maximum. The surgical procedure that has the best results involves a bipolar tenotomy of the affected SCM, followed by casting or bracing to maintain the corrected posture.

Acquired muscular or ligamentous torticollis is managed with local heat, massage, analgesics, muscle relaxants, and a soft cervical collar. Symptoms usually resolve in 7 to 10 days. Notably, however, patients with acquired muscular or ligamentous torticollis experience only mild discomfort. Any child with severe neck pain or tenderness over the vertebra requires immediate cervical immobilization until radiography can be performed to exclude the possibility of vertebral fracture or subluxation.

Drug-induced dystonic reactions are reversed by discontinuing the offending drug and administering intravenous diphenhydramine. The treatment of torticollis arising from other specific diseases should be directed at the cause.

### WHEN TO REFER

- Presence of craniofacial asymmetry
- Radiographic evidence of cervical spine abnormality
- More than 30% restriction in range of motion
- Persistence beyond the first year of life

### WHEN TO ADMIT

- Presence of neurologic deficits
- Severe neck pain
- Point tenderness over the vertebrae

## Chapter 204

# VAGINAL BLEEDING

Maria Trent, MD, MPH; Alain Joffe, MD, MPH

The assessment of vaginal bleeding depends largely on the pubertal status of the patient. In prepubertal girls, vaginal bleeding usually reflects a localized problem in the vagina or uterus. In pubertal girls and young women, the differential diagnosis includes disorders affecting the hypothalamic-pituitary-ovarian (HPO) axis and complications of pregnancy in addition to local causes. In all cases, however, a complete history and thorough physical examination will provide important clues to the diagnosis.

## PREPUBERTAL GIRLS

In utero, maternal estrogen diffuses across the placenta into the fetal circulation. After birth, estrogen levels in the infant fall, resulting in a physiologic vaginal discharge that can be blood tinged or frankly bloody. No treatment except reassurance is necessary, and the discharge usually disappears within 10 days.

Several conditions can result in vaginal bleeding in the prepubertal child, including vulvovaginal infections, excoriations secondary to pruritus, foreign bodies, sexual abuse, trauma (eg, involving a straddle injury during bike riding), tumors, condylomata, hemangiomas, polyps, and coagulopathies. Any suggestion of sexual abuse, such as bruising, hymenal tears, or other signs of trauma, mandates obtaining a careful, nonthreatening history from the child and caretaker to determine the need for a referral to child protective services for full investigation including forensic interview and subspecialty medical evaluation.

Nighttime pruritus may indicate a pinworm infestation. The Scotch tape slide test, to look for pinworm eggs, can help establish *Enterobius vermicularis* infestation. If petechiae or numerous bruises are noted on

physical examination, a platelet count and clotting studies are indicated to screen for a coagulopathy. A foreign body in the vagina should always be considered, even if no history of such exists. Contrary to popular belief, most girls who have bleeding from a foreign body do not have an associated foul-smelling discharge. The physician should also make sure that the bleeding is vaginal in origin, given that a prolapsed urethra can mimic vaginal bleeding.

Excoriation, erythema, or a rash in the perineal area make vaginitis a distinct possibility. If a vaginal discharge is found and microscopic examination demonstrates large numbers of white blood cells, then vaginitis is highly likely. Concern about sexual abuse should prompt cultures for *Neisseria gonorrhoeae* and *Chlamydia trachomatis*. Other bacterial cultures may be necessary. For example, a history of diarrhea in the weeks preceding onset of the bleeding suggests vaginitis caused by *Shigella* organisms. Group A beta-hemolytic streptococcus can also cause vaginitis.

Vaginal bleeding caused by a foreign body or vulvitis will respond to removal of the foreign body and proper perineal hygiene. Occasionally, systemic antibiotics may be necessary. Foreign bodies can often be washed out with a soft, flexible catheter; sharp objects should be removed carefully, under direct visualization. Care should be taken to avoid touching or manipulating the unestrogenized prepubertal hymen as to avoid pain to the child. Referral to a gynecologist may be required if the patient is uncooperative. After removal of a foreign body, bleeding should subside within 10 days. If it does not, then referral to a gynecologist is indicated. The entire foreign body may not have been removed, or a tumor, not readily visualized by the primary care physician, may be the actual cause of the bleeding. Similarly, when treatment of the presumed cause does not end the bleeding, referral for a more thorough examination is indicated.

## PUBERTAL GIRLS

### Evaluation

Abnormal vaginal bleeding in pubertal girls can indicate a variety of disorders. Evaluation of this symptom depends on the nature of the problem: Is she bleeding between normal periods, or have her previously regular menses become more frequent or heavier? A teenager whose prior menses have been regular might possibly begin to have infrequent but heavy menstrual bleeding. In general, normal periods in adult women (measured from the first day of 1 period to the first day of the next), range from 21 to 35 days with a flow of 3 to 7 days. Flow greater than 1 week is considered excessive. A similar cycle pattern is observed in adolescent girls, but cycle length is more variable, especially in the first few years after menarche. Although the normal blood loss during menses is 30 to 40 mL, with an upper limit of 80 mL, the quantity of blood loss is difficult to assess by history unless the patient reports very light flow. History should include an assessment of menstrual pattern and the quantity of pads or tampons used. Although research has demonstrated the value of pictorial assessment to determine menstrual blood loss, laboratory assessment of hemoglobin,

hematocrit, or both is useful for determining if significant blood loss resulting in anemia has occurred.

Normal menstrual function requires that the HPO axis function properly. Follicle-stimulating hormone (FSH) causes maturation of ovarian follicles, which produce estrogen. Rising levels of estrogen stimulate the endometrial lining of the uterus to proliferate and, at the same time, induce a midcycle surge of luteinizing hormone (LH) that causes the primary follicle to release an ovum, after which LH and FSH levels fall. The remnants of the follicle (*corpus luteum*) now produce progesterone, which converts the proliferative endometrium to a secretory phase. At the end of a normal cycle, the corpus luteum involutes, and both estrogen and progesterone levels fall. The endometrial lining is shed, and bleeding occurs.

In adolescents, especially young adolescents, the HPO axis is relatively immature and highly sensitive to disturbance by several endogenous and exogenous factors; this perturbation leads to irregular bleeding. Among young adolescents (but in some older adolescents as well), the axis has not yet matured, and most cycles are anovulatory. Thus the endometrium proliferates under estrogen stimulation from the maturing follicle, but the midcycle LH surge is absent, ovulation does not occur, and the progesterone-secreting corpus luteum never forms. Toward the end of the cycle, the follicle involutes, estrogen levels fall, and bleeding occurs. Influenced by estrogen only, endometrial shedding is incomplete and irregular, accounting for the excessive bleeding of anovulatory cycles. Alternatively, fluctuating estrogen levels during an anovulatory cycle result in estrogen withdrawal bleeding. The occasional ovulatory cycle helps stabilize endometrial growth, and because the corpus luteum produces progesterone, a more organized withdrawal bleed occurs. Hence, any condition that increases the frequency of anovulatory cycles is more likely to produce the kind of uterine bleeding that prompts the teenager to seek medical care.

Most teenagers who seek evaluation for genital bleeding in the first few years after menarche will have abnormal uterine bleeding (AUB) secondary to an immaturity of the HPO axis, with resultant anovulatory cycles. Because this is a diagnosis of exclusion, the primary care physician should search for other causes that affect the integrity of the HPO axis and can mimic AUB from this cause. Anovulatory cycles may also occur in patients with a mature HPO axis who have disorders such as polycystic ovary syndrome, thyroid disease, or conditions resulting in hypothalamic amenorrhea (emotional stress, eating disorders, chronic illness, or intense athleticism). Additional causes of abnormal bleeding in this age group include disorders of pregnancy, other endocrine abnormalities, cervicitis, vaginitis, pelvic inflammatory disease, other sexually transmitted infections, foreign bodies, tumors, coagulopathies, drugs, and systemic disorders (Box 204-1). Heavy bleeding at menarche, significant anemia, or the need to be hospitalized to control the bleeding all increase the likelihood that a coagulopathy or another pathologic condition is the cause of the bleeding. Family history, however, has been shown to be a better predictor of coagulopathy than menstrual

history. While the International Federation of Gynecology and Obstetrics [FIGO] and the American College of Obstetrics and Gynecology (ACOG) have disregarded many of the old terms used to describe menstrual abnormalities and developed a new nomenclature for use in adult women termed PALM-COEIN (PALM [structural causes: poly, adenomyosis, leiomyoma, malignancy and hyperplasia]; COEIN [nonstructural causes: coagulopathy, ovulatory dysfunction, endometrial, iatrogenic, and not yet classified]), it is important to adequately explore the diagnostic entities common in pubertal girls such as anovulatory bleeding, pregnancy, sexually transmitted infections, and von Willebrand disease.

### History

Most causes of vaginal bleeding or abnormal uterine bleeding (see Box 204-1) can be ruled out by history and physical examination. Maternal support during the initial history taking can be useful. Many mothers track the menstrual periods of their adolescent daughters, especially in the first years after menarche, and are keenly aware of the amount of bleeding based on the quantity of feminine products purchased, stained laundry, evidence of fatigue, and general level of their activity and behavior. A mother can often provide detailed family medical histories for first-degree female relatives, as well as that of her daughter.

Certain key aspects of the history may be difficult to obtain. A young woman may hesitate to reveal that she has engaged in sexual intercourse or that she has been sexually abused. The patient should be interviewed alone regarding sexual activity, sexually transmitted infections (including associated symptoms such as cramping, vaginal discharge, and dyspareunia), abuse, stress, weight changes and eating habits, participation in sports and other activities, chronic illnesses, other bleeding problems, medication use (particularly contraceptives), and substance use patterns. If a discharge is foul smelling and bloody, then a foreign body or retained tampon is likely; however, necrotic tumors can result in similar bleeding patterns. Pruritus or dysuria suggests vaginitis or cervicitis as the cause of the bleeding. Bleeding between periods is common during the first 2 or 3 cycles of oral contraceptive use and generally does not require any additional therapy; however, cervicitis secondary to *N gonorrhoeae* or *C trachomatis* infection or vaginitis secondary to *Trichomonas vaginalis* may also result in intermenstrual spotting. Young women who receive depot medroxyprogesterone acetate (Depo-Provera) injections often have frequent and irregular periods of excess bleeding, particularly in the first months after beginning use of this contraceptive method. Teenagers who forget to take 1 or 2 oral contraceptive pills may also have some bleeding. Occasionally, women may have a small amount of bleeding or spotting after sexual intercourse, and some will have spotting around the time they ovulate. A complete family history is important to determine if other family members have any kind of bleeding problem. Complications of pregnancy (ectopic pregnancy or incomplete abortion) are more likely if a history of 1 or 2 missed periods exists, if the prior menstrual

- Platelet inhibitors

period was lighter than normal, if other symptoms of pregnancy are present (breast tenderness or nausea), or if the bleeding is accompanied by crampy, lower abdominal pain. A history of passing tissue or tissue present in the vaginal canal is also suggestive of complications of pregnancy. Blood dyscrasias, such as thrombocytopenia or von Willebrand disease, can cause heavy vaginal bleeding without other cutaneous manifestations of bleeding. Symptoms of endocrine disorders, such as cold intolerance, polyuria, nipple discharge, headache, acne, and increased facial hair, can be easily assessed using a comprehensive review of systems.

**Physical Examination**

The physical examination should include measurement of height, weight, and blood pressure, as well as thorough palpation of the thyroid gland. Visual field and funduscopic examinations are necessary to help rule out a prolactinoma. Increased facial hair is consistent with polycystic ovaries or an adrenal tumor. Striae suggest Cushing disease. An enlarged clitoris is consistent with an androgen-secreting tumor or late-onset 21-hydroxylase deficiency. Normal findings on physical examination, including pelvic examination, help rule out the many causes of vaginal bleeding or abnormal uterine bleeding listed in Box 204-1. Vulvar

or vaginal bruising or lacerations suggest the probability of sexual abuse, although the most common finding after sexual abuse is a normal examination without any evidence of trauma. Lack of abdominal pain with adnexal or cervical motion tenderness excludes pelvic inflammatory disease. If the ovaries are of normal size, then ovarian tumors or cysts are unlikely sources of the bleeding. A minimally enlarged uterus, consistent with early pregnancy, may not be noted by an inexperienced examiner. Endometrial polyps or submucous leiomyomas are distinctly unusual in women younger than 20 years, and they cannot be palpated by the examiner on the usual pelvic examination. With a patient who has an intractably heavy flow, these entities should be considered.

### Laboratory Tests

For most cases of vaginal bleeding, relatively few laboratory tests are needed. A complete blood count with indices provides an objective measurement of the amount and duration of bleeding and guides the treatment approach for patients with an otherwise negative evaluation. A urinalysis and urine pregnancy test should also be obtained. Bleeding associated with crampy lower abdominal pain may indicate ectopic pregnancy, and a quantitative serum pregnancy test is indicated. Screening for *N gonorrhoeae*, *C trachomatis*, trichomonas, and bacterial vaginosis is indicated for sexually active patients or when there is any suspicion of sexual abuse. A pelvic sonogram is indicated if ectopic pregnancy is suspected, if a pelvic mass is found on bimanual examination, or if the pelvic examination is difficult.

Thyroid-stimulating hormone function tests, prolactin, LH and FSH levels, and coagulation tests should be ordered if hormonal therapy is contemplated. Any evidence of hyperandrogenism necessitates measurement of androgens, which may initially include free and total testosterone, and dehydroepiandrosterone sulfate. Coagulation tests such as a prothrombin time, partial thromboplastin time, von Willebrand panel, and platelet aggregation studies are indicated if the patient has profuse hemorrhage, menorrhagia at menarche, a family history of bleeding disorders, or unexplained heavy vaginal bleeding. Measures of iron stores (eg, ferritin, reticulocyte count, hemoglobin content) may also be useful in managing iron deficiency even in the absence of anemia.

### Management

Sexually transmitted infections are easily diagnosed and can usually be treated with antibiotics. The complications of pregnancy, such as threatened or spontaneous abortion, can be managed in the outpatient setting. However, a physician experienced in the management of early pregnancy should be consulted. For patients with bleeding disorders, consultation with a hematologist may be required.

Most cases of vaginal bleeding in adolescent girls are caused by anovulatory cycles. In other instances, the physician must manage the bleeding without knowing the cause. Treatment decisions can be guided using the patient's clinical symptoms and the results of basic laboratory testing. Although some physicians

may feel comfortable using hormonal therapy, others may prefer the guidance of a more experienced physician. Because many patients with DUB are early adolescents accompanied by their parents, the primary care physician should include the parents in the decision to begin hormonal treatment in a non-sexually active patient. Assuring the parents that combined oral contraceptives (COCs) are, in this instance, being used as treatment; COCs are the most convenient way to package and deliver hormonal treatment; short-term use of COCs for 3 to 6 months is anticipated; and close follow-up will be provided during the treatment period, will often alleviate concerns about hormonal treatment and prevent rejection of these methods by the family. All patients with abnormal vaginal bleeding should be instructed to maintain a menstrual calendar to facilitate follow-up management.

Mild cases of AUB that do not result in anemia and that do not greatly upset the patient and her parents can be managed expectantly with no immediate, specific therapy. Those who have mild anemia (hemoglobin value 11–12 g/dL) should receive iron supplementation. Some problems will resolve in 3 or 4 cycles. For a sexually active patient, oral contraceptive pills can be prescribed to treat the bleeding, as well as to provide contraception. Nonsteroidal anti-inflammatory drugs (NSAIDs), such as ibuprofen or naproxen, can also be used for their demonstrated antiprostaglandin effects. It should be noted that patients with von Willebrand disease or other hemostatic abnormalities may have increased bleeding if NSAIDs are prescribed. Patients with mild bleeding should be reevaluated in 6 to 8 weeks.

In addition to iron supplementation, hormonal therapy is indicated in teenagers who have moderate AUB (enough to cause a decrease in hemoglobin to less than 11–12 g/dL). Girls who have menses every 1 to 3 weeks also need treatment. Treatment includes COCs or progestin alone. As previously mentioned, COCs are easier to use (1 pill is taken daily every day of the month). If the patient has a condition in which COCs are contraindicated or this method is rejected by the patient or her parents, then medroxyprogesterone 10 mg orally can be given daily for 10 to 14 days, beginning on the first day of each month (calendar method) or on the fourteenth day of the menstrual cycle (day 1 being the first day of bleeding). The patient with moderate bleeding should be reassessed in 4 to 6 weeks.

Patients with severe prolonged heavy AUB accompanied by a drop in hemoglobin to 10 g/dL or less need to be treated more aggressively. In this instance, adolescent medicine or gynecologic consult should be sought, clotting studies obtained, and hospitalization strongly considered. For patients with severe bleeding, COCs (1 tablet taken twice daily for 3 to 4 days) will generally stop the bleeding. However, prescribing a COC such as ethinyl estradiol-norgestrel-28 every 4 hours may be necessary initially until the bleeding stops, then every 6 hours for 24 hours, then every 8 hours for 4 days, and then twice daily to complete 3 weeks of hormonal therapy. Antiemetic medications may be required to counteract the side effects of the high levels of estrogen contained in this regimen. A

withdrawal bleed will occur 2 to 4 days after completion of this initial course of therapy. Patients with significant AUB should avoid the placebo pills contained in the COC pill packs and remain on continuous COCs until the hemoglobin and hematocrit begin to normalize. Iron and folic acid supplementation should be included as a part of the therapeutic plan.

The need for blood transfusion will depend on the hemodynamic stability of the patient. Although some physicians prefer to use conjugated estrogens (25 mg intravenously every 4 hours) to stop the bleeding, use of ethinyl estradiol-norgestrel-28 or a similar COC given 6 times a day and then gradually tapered to once a day over the next 7 to 10 days will usually stop the bleeding. Endometrial biopsy or dilation and curettage is rarely indicated. Even when these measures succeed in controlling the vaginal bleeding, affected adolescents require long-term, close follow-up because an appreciable number of them will continue to have menstrual abnormalities.

### WHEN TO REFER

- Patient is experiencing severe bleeding or initial attempts to control the bleeding by the primary care physician have failed.
- Vaginal bleeding seems to be secondary to a chronic illness that the primary care physician is unable to manage.
- Primary care physician feels uncomfortable performing a pelvic examination.
- Long-term hormonal therapy is required.
- Evidence of anatomical abnormality exists.
- Evidence of a complicated endocrine disorder exists.
- Evidence of a coagulopathy exists or additional guidance is required for further evaluation of a coagulation or hemostatic disorder.
- Evidence of a malignancy exists.
- Evidence of sexual abuse exists.

### WHEN TO ADMIT

- Patient shows evidence of hemodynamic instability.

## Chapter 205

## VAGINAL DISCHARGE

Linda M. Dinerman, MD, PC; Alain Joffe, MD, MPH

Vaginal discharge is a common complaint to pediatricians. However, the presence of discharge is not necessarily abnormal; this symptom may represent the vagina's response to changes in estrogen levels, and the pediatrician need only reassure the patient and her parents. In most circumstances, the age of the patient, her pubertal status, and whether she has ever had sexual intercourse are key elements in sorting out the cause of the discharge.

### NEWBORN PERIOD

In utero, the vaginal epithelium of the neonate is stimulated by maternal hormones that cross the placenta into the fetal circulation. After delivery, these hormone levels fall rapidly, and the parents may note a thick, grayish-white, mucoid discharge from the neonate's vagina. In many instances, the discharge is blood tinged or even grossly bloody. No treatment is needed, and the discharge usually resolves by 10 days of age.

## PREPUBERTAL GIRLS

The genital area of prepubertal girls is more susceptible to infection than that of older, pubertal girls. The labial folds are smaller and lack pubic hair, and the distance between the vagina and the rectum is relatively short compared with adolescents and adults. Low levels of circulating estrogen render the vaginal mucosa relatively thin and susceptible to irritation or infection. The alkaline pH (approximately 7.0) of the vaginal secretions affords a hospitable environment to bacteria, which together with poor perineal hygiene, allows fecal flora to establish themselves more easily in the genital area. Box 205-1 lists causes of vaginal discharge in prepubertal girls.

### Evaluation

When evaluating a premenarchal girl who has vaginal discharge, the physician should inquire about her hygiene. Wiping from the rectum toward the vagina brings intestinal flora to the vaginal introitus. Use of chemicals such as bubble baths, deodorants, or strong detergents to launder underwear can irritate the vulva and vagina. Occlusive nylon or rayon underwear provides a moist environment for potential pathogens, and the material itself can be an irritant. Although accounting for less than 5% of cases of vaginal

discharge, the possibility that the child or an abuser placed a foreign body, such as toilet paper, a coin, a small toy, or other objects, in her vagina should be considered. In such cases, the child has a discharge that can range from scant to abundant; can be white, brown, or bloody; and is frequently malodorous.

The parents should be asked about recent or concomitant illness. For example, vaginal discharge is associated with *Streptococcus pyogenes* infection (with or without scarlet fever) and with *Shigella* infection, occurring coincident with or after an episode of diarrhea. Systemic illnesses such as varicella also may be associated with vaginal discharge. Rectal infestations with *Enterobius vermicularis* (pinworms) can lead to vaginitis if the eggs are deposited around or in the vagina. A history of nocturnal itching accompanying vaginal discharge suggests this diagnosis. *Candida vulvovaginitis* is an uncommon cause of vaginal discharge or vulvovaginitis in prepubertal girls unless the child has recently taken antibiotics, has diabetes mellitus, is still in diapers, or is immunocompromised.

Sexually transmitted organisms, such as *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, and *Trichomonas vaginalis*, are known to cause vaginal infections in prepubertal girls. Whereas *N gonorrhoeae* clearly causes vaginal discharge, evidence that *C trachomatis* alone does so is limited. The possibility of sexual abuse should always be considered in the evaluation of any child with vaginal discharge.

Although these other entities should be considered carefully as the physician evaluates the young patient, nonspecific vaginitis, in which no clear causative agent for the discharge can be established, accounts for 25% to 75% of cases of vulvovaginitis. Rare causes of discharge include polyps or tumors; ectopic ureters, which drain urine into the vagina, resulting in a wetness that is mistaken for discharge; a draining pelvic abscess; or a prolapsed urethra, often associated with a bloody discharge.

The physical examination should include the entire genital and rectal area. The condition of the vulva, urethral meatus, and vaginal introitus should be noted. Infections in prepubertal girls usually involve the vulva as opposed to only the vagina. The presence of bruises, lacerations, or scrapes in the genital area is suggestive of sexual abuse, although it must be remembered that in most cases of child sexual abuse, the examination reveals no evidence of trauma. Excoriations around the rectum or vagina suggest itching caused by pinworms. A rash that spares skin folds is consistent with an irritative cause; one that is predominantly within the skin folds suggests candidiasis.

Having the girl sit on her mother's lap with her legs spread so that they dangle outside her mother's legs will often afford the examiner a clear view of the vulva and vaginal introitus. Alternatively, she may lie on her back in the frog-leg position or face down on the examining table in the knee-chest position. Care should be taken to avoid touching or manipulating the sensitive unestrogenized hymen of a prepubertal child to minimize pain. If a foreign body is thought to be present (because of a thick discharge that is often bloody and sometimes foul smelling) but not visualized, then irrigating the vagina with a soft, flexible catheter and

### BOX 205-1 Causes of Vaginal Discharge in Prepubertal Girls

- Nonspecific vaginitis (the most common cause)
- Irritative (bubble baths, sand); the vulva is often involved as well. Nonabsorbent, occlusive clothing such as nylon undergarments, tights, bathing suits also irritate the vulva, leading to skin breakdown and infection. Although uncommon, *Candida* species infections can arise under these circumstances.
- Poor perineal hygiene
- Foreign body
- Associated systemic illness (group A streptococci, varicella)
- Other respiratory pathogens (eg, *Haemophilus influenzae*) may also cause discharge
- Enteric infections
- *Escherichia coli* with foreign body
- *Shigella* organisms
- *Yersinia* organisms
- *Enterobius vermicularis*
- Sexually transmitted infections (strong presumption of sexual abuse)
- *Neisseria gonorrhoeae*
- *Trichomonas vaginalis*
- *Chlamydia trachomatis* (Whether this organism alone can cause discharge is unclear. *C trachomatis* is often isolated in conjunction with *N gonorrhoeae*.)
- Primary vulvar skin disease
- Tumor, polyps (rare)

tepid saline solution will often flush out bits of toilet paper or small objects.

If sufficient vaginal discharge is present, then several drops of the secretion should be placed on 2 glass slides. If the discharge is scant, then a saline-moistened cotton swab can be introduced into the vagina to obtain samples for the glass slides. Several drops of normal saline solution should be added to 1 slide to create a wet preparation. Several drops of 10% potassium hydroxide should be added to the second slide, which should then be gently heated to dissolve epithelial cells, allowing visualization of hyphae. Slides should be examined, as indicated in Table 205-1. If indicated, cultures for *N gonorrhoeae* and *C trachomatis* should be performed; alternatively, evaluation with nucleic acid amplification tests may be easier to perform and provide more sensitive testing. A piece of cellophane tape with its sticky side applied to the perianal area and then onto a glass slide for microscopic examination may reveal the typical eggs of *E vermicularis*.

### Management

If the history or physical examination suggests an irritative origin, then parents should discontinue the offending agent and have the child wear cotton underpants. Sitz baths will provide temporary relief until natural healing takes place. Removal of a foreign body will result in rapid improvement and cessation of the discharge. Pinworm infestations should be treated in the usual manner. Infections caused by poor personal hygiene will respond to the general measures just listed, coupled with instructions about proper perineal hygiene. If the discharge is associated with another infection (such as *S pyogenes* or *Shigella* organisms), then it will disappear as the underlying infection is treated.

When the organism causing the vaginal discharge is found to be sexually transmitted, more comprehensive evaluation and treatment are required. Appropriate antibiotic treatment should be prescribed and a report to child protective services made.

Nonspecific vaginitis will usually respond to thorough perineal hygiene, sitz baths, and mild soaps. Patients should be advised to wear white cotton underpants and loose-fitting pants or skirts, to avoid nylon tights and tight pants, to avoid sitting for long periods in nylon bathing suits, and to wipe only from front to back. For persistent cases, the condition can be treated with amoxicillin, amoxicillin clavulanate, a cephalosporin, or clindamycin in standard childhood doses for 10 to 14 days. Alternatively, a 1- to 2-month daily low-dose antibiotic may be helpful. If these approaches are unsuccessful, then antibiotic creams (mupirocin, gentamicin, metronidazole, or clindamycin) or estrogen creams may be used. If symptoms persist, the patient should then be referred to a pediatric gynecologist.

### PUBERTAL AND POSTPUBERTAL ADOLESCENTS

With the onset of puberty, circulating estrogen and progesterone levels rise, stimulating vaginal mucus production and an increase in the turnover of vaginal

epithelial cells. Bartholin and sebaceous glands are also stimulated. Generally, the clear mucoid discharge that results will not cause problems. The amount of secretion, however, can increase with sexual excitement, as well as midway through a normal menstrual cycle. Discharge is particularly prominent at the onset of puberty (physiologic leukorrhea). Examination of a wet preparation will reveal vaginal epithelial cells only. The high protein content of this discharge, absorbed onto underwear, causes yellow staining. Traditionally, occlusive nylon or rayon underpants have been alleged to cause a nonspecific vaginal discharge; however, that association may be spurious.

A wide variety of organisms are normally found in the vagina. These organisms, especially the lactobacilli, help maintain the normal acidic pH of the vagina, which resists infection. Some of the organisms that cause vaginitis and vaginal discharge in this age group are sexually transmitted or associated with sexual activity. Because many teenagers fear admitting to sexual intercourse, a negative response to queries about sexual activity should not rule out consideration of a sexually transmitted organism as the cause of the discharge. Sexual abuse and the presence of a foreign body (eg, a retained tampon or condom) should also be considered. If a sexually transmitted organism has caused the discharge, then the patient's sexual partner should be notified and treated. Patients should refrain from sexual intercourse until they complete treatment. Otherwise, reinfection from the partner may occur. Use of spermicides or douching can cause vaginitis.

The organisms and conditions commonly responsible for vaginal infections or vaginal discharge in pubertal young women and their treatments are listed in Table 205-1. Although the characteristics of each type of infection are said to be typical, the discharge observed on examination does not always fit these classic presentations. The laboratory methods outlined in Table 205-1 therefore are of considerable diagnostic utility. However, they are not 100% sensitive. *T vaginalis* may not be noted during microscopic examination even if the vaginal fluid is examined immediately under the microscope to avoid drying of the organisms. The vaginal wet preparation is 64% to 80% sensitive at identifying trichomonads compared with culture, depending on the presence of symptoms and the experience of the microscopist. Nucleic acid amplification tests (NAAT) are the most sensitive commercial tests for detecting trichomonas infection but are not available as a point-of-care test. Other FDA-cleared tests are the OSOM Trichomonas Rapid Test (results in 10 minutes) and the Affirm VP III (results in 45 minutes). *T vaginalis* can be found on Pap tests but the Pap test is not considered a diagnostic test for trichomoniasis. Although the Centers for Disease Control and Prevention consider a Gram stain the gold standard for the diagnosis of bacterial vaginosis, it is not widely used in clinical practice. In the absence of a Gram stain, 3 of 4 clinical criteria should be met to make the diagnosis: (1) homogeneous, thin white discharge evenly coating the vaginal walls; (2) clue cells on microscopic examination; (3) vaginal fluid pH higher than 4.5; (4) positive "whiff test"—a fishy odor

**Table 205-1** Major Causes of Vaginal Discharge in Pubertal Girls

AGENT	DISCHARGE	ODOR; pH	DYSURIA; PRURITUS	OTHER CLUES	DIAGNOSIS	TREATMENT <sup>a</sup>
<i>Candida albicans</i>	Thick, white, curdlike, cheesy	None usually; pH 4.5 (obtained from midvagina with nitrazine paper)	Dysuria frequent; pruritus (4+)	Vulva affected; association with use of some oral contraceptives and, in some women, with antibiotic use	Hyphae on potassium hydroxide examination	A variety of effective treatments are available for vaginal candidiasis, including creams, suppositories, and intravaginal tablets. Three-, 5-, and 7-day therapies offer no advantage over single-day treatments. Fluconazole 150 mg orally as a single dose is as effective as other regimens; however, more systemic side effects may occur. Ultimately, the best treatment is a combination of patient preference, what treatments are covered by her insurance policy, and whether it is less expensive or more convenient for the patient to obtain a prescription medication or purchase an over-the-counter treatment.
<i>Trichomonas vaginalis</i>	Frothy; yellow-green or gray	Foul smelling; pH 5.2–5.5	Dysuria frequent; pruritus	Low abdominal pain; “strawberry” cervix; punctate vaginal hemorrhages	Motile trichomonads on wet preparation; avoid drying specimen; NAAT most sensitive; other antigen detection tests also available	Metronidazole 2 g orally in a single dose or tinidazole 2 g orally in a single dose. Alternative regimen is metronidazole 500 mg twice daily for 7 days. If failure occurs with either of the indicated regimens (and reinfection is excluded), the patient should be treated with metronidazole 500 mg twice daily for 7 days. Repeated failures should be treated with tinidazole or metronidazole at 2 g orally for 7 days. The patient should be advised to avoid alcohol until 24 hours after completion of therapy with metronidazole or 72 hours after treatment with tinidazole.
Bacterial vaginosis <sup>b</sup>	Homogeneous, thin, white discharge that smoothly coats the vaginal walls	A fishy odor of vaginal discharge before or after addition of 10% KOH (ie, the whiff test); pH >4.5	No dysuria; slight pruritus	Occurs in association with anaerobes and <i>G vaginalis</i>	Clue cells on wet preparation (bacteria-coated epithelial cells); affirm VP III & OSOM BV Blue tests are commercially available tests when microscopy is not available	Metronidazole 500 mg orally twice daily for 7 days, metronidazole gel 0.75% 1 full applicator (5 g) intravaginally once daily for 5 days or clindamycin cream 2%, 1 full applicator (5 g) intravaginally every night at bedtime for 7 days. Alternative regimens include tinidazole 2 g orally once daily for 2 days or tinidazole 1 g orally once daily for 5 days or clindamycin 300 mg orally twice daily for 7 days or clindamycin ovules 100 mg intravaginally 1 at bedtime for 3 days. The patient should be advised to avoid alcohol until 24 hours after completion of therapy with metronidazole or 72 hours after treatment with tinidazole.

<sup>a</sup>Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines. *MMWR Recomm Rep*. 2015;64(RR-3):1–137.<sup>b</sup>Must have 3 of these 4 criteria to make diagnosis.Data from Amsel R, et al. *Am J Med*. 1983;74:14; Brunham RC, et al. *N Engl J Med*. 1984;311:1; Rein MF, Chapel TA. *Clin Obstet Gynecol*. 1975;18:73; and Sobel J. *N Engl J Med*. 1997;337:1896.

to the vaginal discharge before or after the addition of 10% KOH. A DNA probe-based test, as well as a card test to detect increased pH and trimethylamine and proline-aminopeptidase, may also be useful in the diagnosis of bacterial vaginosis.

The role of *N gonorrhoeae* and *C trachomatis* in causing vaginal discharge has been reassessed recently. The presence of yellow vaginal discharge on speculum examination has been associated with infection by either organism; in contrast, neither profuse vaginal discharge nor a foul or fishy odor predicted infection with either. Nonetheless, because sexually transmitted infections often co-occur, appropriate screening tests for *N gonorrhoeae* and *C trachomatis* should be part of the evaluation of vaginitis if *T vaginalis* is found or if the patient reports a new sexual partner.

Bacterial vaginosis is a complex syndrome characterized by decreased *lactobacilli* and increased concentrations of several anaerobic microorganisms. The pathogenesis of this disorder continues to be poorly understood. Bacterial vaginosis is associated with having multiple sex partners, douching, smoking, and the presence of sexually transmitted infections. However, because it sometimes occurs in women who have never had sexual contact, bacterial vaginosis is not considered a sexually transmitted infection. Current evidence indicates that women who have bacterial vaginosis are at increased risk for developing pelvic inflammatory disease after instrumentation of the genital tract and, if pregnant, are more likely to deliver a premature infant or experience postpartum complications. Therefore, prompt treatment is essential. Treatment of sexual partners is not currently recommended because it does not affect the disease process.

Occasionally, herpesvirus infections of the vulvovaginal area or cervix (or both) are associated with vaginal discharge. Typically, pain or a burning sensation is felt in the genital area. The vulva is reddened, and groups of small vesicles are noted on the vulva, in the vagina, or on the cervix. If the vesicles have ruptured, then the examiner sees only small ulcerations. Inguinal adenopathy, fever, and malaise are usually present if this attack is the first one.

A teenager who has a persistent discharge that is unresponsive to therapy may not be complying with treatment or may have become reinfected by an untreated partner. If such is not the case, and if *N gonorrhoeae*, *C trachomatis*, and *T vaginalis* are excluded, and the discharge does not appear to fit any of the causes described earlier, then a trial of sitz baths, use of cotton as opposed to nylon underwear, and careful attention to perineal hygiene are warranted. If symptoms persist, then the patient should be referred to an adolescent medicine specialist or a gynecologist.

Candidal infections can be especially difficult to treat and may recur. Factors that predispose to candidiasis include oral contraceptive use, broad-spectrum antibiotic use, and diabetes mellitus. In cases of recurrent vulvovaginal candidiasis, either topical therapy for 7 to 14 days or oral fluconazole 150 mg repeated 72 hours after the first dose is recommended as initial

treatment. If more intensive treatment is warranted, a recent study of adult women with recurrent vulvovaginal candidiasis demonstrated significant reduction of symptoms among those treated with oral fluconazole 150 mg once weekly for 6 months after initial treatment of 1 dose every 3 days for 3 doses. A variety of monthlong antifungal treatments have been successful; however, intravaginal treatment over a long period is inconvenient for most patients. Although long-term ketoconazole has been used to suppress recurrent infection, hepatotoxicity is a concern. Male sexual partners should also be treated if they have any signs or symptoms of penile candidal involvement.

### WHEN TO REFER

- Physician is uncomfortable with evaluating genital complaints in prepubertal girls
- Physician lacks experience in performing pelvic examinations
- Evaluation yields evidence of sexual abuse
- Discharge persists despite seemingly appropriate therapy

## Chapter 206

# VOMITING

Martin H. Ulshen, MD; Nancy McGreal, MD

Vomiting, a common symptom of acute and chronic illness in childhood, is an active process requiring coordination between autonomic and somatic nervous systems. It must be distinguished from regurgitation, which is passive reflux of gastric contents into the esophagus and mouth through a relaxed lower esophageal sphincter. Vomiting is usually preceded by nausea in association with increased salivation, pallor, and diaphoresis. Retching (coordinated contraction of abdominal and intercostal muscles, as well as the diaphragm, with simultaneous closure of the glottis) immediately precedes the actual vomiting. Reflux of duodenal contents into the stomach, resulting from nonperistaltic contractions of the small bowel, is associated with elevation and relaxation of the proximal stomach and inhibition of antral motility. Increased intragastric pressure from contraction of the abdominal wall musculature and lowering of the diaphragm then result in expulsion of stomach contents. Brainstem signals transmitted to a cerebral site, not yet identified, result in the conscious sensation of nausea. Psychogenic causes of nausea (eg, anticipatory nausea) presumably occur directly at a cerebral site.

Five classes of stimuli provoke nausea and vomiting: (1) toxic substances within the lumen of the gastrointestinal tract, which initiate release of mediators by enteroendocrine cells (including 5-hydroxytryptamine, substance P, and cholecystikinin [CCK]); (2) absorbed or parenterally administered toxins, which act directly on the area postrema (also referred to as the *chemoreceptor trigger zone*—a major lower brainstem center for coordination of drug-induced vomiting); (3) pathologic processes in viscera (eg, gastrointestinal dilation or inflammation, renal failure); (4) central nervous system (CNS) stimuli (eg, fear, anticipatory nausea, raised intracranial pressure); and (5) vestibular stimuli (eg, motion sickness) that result in nausea and vomiting by way of the autonomic nervous system. Motor outputs of retching and vomiting are coordinated by brainstem nuclei (known in the past as the “vomiting center”). Vomiting provoked by CNS stimuli may occur with little or no prodrome of retching or nausea.

Understanding the role of neurotransmitters as mediators in the initiation of vomiting has led to a range of new antiemetics. The area postrema, as well as autonomic pathways and other brainstem nuclei, is rich in enkephalins, 5-hydroxytryptamine type 3 (5-HT<sub>3</sub>) receptors, dopamine receptors, and neurokinin-1 (NK<sub>1</sub>) receptors. Enkephalins and 5-HT both stimulate release of dopamine. Dopamine receptor, 5-HT<sub>3</sub>, and NK<sub>1</sub> antagonists have been successful in the treatment of chemotherapy-induced nausea and vomiting. Antihistamines and anticholinergics prevent motion sickness by acting at histamine (H<sub>1</sub>) and muscarinic cholinergic receptors, respectively, in the nucleus

ambiguus in the lower brainstem and in the lateral vestibular nucleus in the midpons.

## CAUSES AND DIFFERENTIAL DIAGNOSIS

Box 206-1 lists the most frequent causes of vomiting in infants and children. In infancy, regurgitation, or spitting up, is very common and most often a developmental event that has no sequelae and gradually resolves. Pathologic gastroesophageal reflux (ie, gastroesophageal reflux disease) is defined by the association of regurgitation with complications, including esophagitis (sometimes with anemia or stricture), recurrent apnea, aspiration pneumonia, or failure to thrive. Bilious vomiting, especially when associated with the first vomitus, usually occurs only with ileus or intestinal tract obstruction below the ampulla of Vater (second portion of the duodenum). In newborns, bilious vomiting can be associated with necrotizing enterocolitis. In older children who vomit persistently, reflux of bile from the duodenum into the stomach may lead to bilious vomiting without gastrointestinal tract obstruction. Projectile vomiting commonly occurs with pyloric stenosis. When this condition persists, however, gastric atony may eliminate the projectile character. A succussion splash (the splashing sound present when a patient who has fluid in a hollow organ is gently shaken on physical examination) may be present, as in other causes of gastric outlet obstruction. Vomiting associated with increased intracranial pressure may be projectile and may take place in the absence of nausea or retching.

Persistent vomiting in a newborn or young infant who has no evidence of infection usually suggests a congenital gastrointestinal anomaly, inborn error of metabolism, or CNS abnormality such as hydrocephalus or subdural effusion. If the history and physical examination results do not suggest a cause, then evaluating all 3 possibilities simultaneously is best. When the sudden onset of bilious vomiting develops in a previously well newborn, especially within the first few days of life, the physician must consider a malrotation with secondary midgut volvulus. Midgut volvulus is a surgical emergency requiring early diagnosis and surgical intervention. In a sick newborn, the diagnosis of necrotizing enterocolitis must be considered in the event of bilious vomiting, especially with blood in the stool. Beyond the first week of life but within the first 2 months, pyloric stenosis is the most common cause of persistent vomiting in an otherwise well infant. In the older infant or child, the entire spectrum of causes of vomiting listed in Box 206-1 should be considered. Patients who have celiac disease may occasionally have minimal or no diarrhea but prominent vomiting. When an older child exhibits acute vomiting and somnolence, the physician should always consider drug overdose (especially acetaminophen, aspirin, or iron), meningoencephalitis, and inborn errors of metabolism (especially mitochondrial fatty acid oxidation) in the differential diagnosis. Persistent or recurrent vomiting without other symptoms may be the major manifestation of an emotional disorder in childhood. Therefore, a complete psychosocial history is an important part of the evaluation.

**BOX 206-1 Causes of Vomiting (Arranged by Usual Age of Earliest Occurrence)****INFANCY/EARLY CHILDHOOD****Gastrointestinal****Congenital**

- Regurgitation—gastroesophageal reflux (developmental or pathologic)
- Atresia—stenosis (tracheoesophageal fistula, antral web, intestinal atresia, annular pancreas)
- Gastrointestinal tract duplication
- Volvulus (secondary to an error in rotation and fixation or to Meckel diverticulum)
- Congenital bands
- Meconium ileus (cystic fibrosis), meconium plug
- Hirschsprung disease

**Acquired**

- Acute infectious gastroenteritis
- Food allergy, cow milk protein intolerance, eosinophilic gastroenteritis
- Eosinophilic esophagitis
- Pyloric stenosis
- Intussusception
- Celiac disease—risk is inherited, but clinical manifestations occur only after introduction of gluten in diet
- Incarcerated hernia—inguinal, internal secondary to old adhesions
- Postviral gastroparesis<sup>a</sup>
- Adynamic ileus—the mediator for many nongastrointestinal causes of vomiting
- Neonatal necrotizing enterocolitis
- Chronic granulomatous disease with gastric outlet obstruction

**Nongastrointestinal**

- Infectious—otitis, urinary tract infection, pneumonia, upper respiratory tract infection, sepsis, meningitis
- Metabolic—aminoaciduria and organic aciduria, galactosemia, fructosemia, adrenogenital syndrome, renal

tubular acidosis, hyperammonemia, disorders of fatty acid oxidation (eg, medium-chain acyl-coenzyme A dehydrogenase deficiency), mitochondrial disease

- Central nervous system—trauma, tumor, infection, increased intracranial pressure, ventriculoperitoneal shunt failure, diencephalic syndrome, rumination, autonomic responses (pain, shock), anticipatory nausea and vomiting

**CHILDHOOD/ADOLESCENCE****Gastrointestinal**

- Appendicitis
- Food poisoning (staphylococcal, clostridial)
- Peptic disease—ulcer, gastritis, duodenitis, *Helicobacter pylori* infection
- Trauma—duodenal hematoma, traumatic pancreatitis, perforated bowel
- Pancreatitis—viral, trauma, drug induced, cystic fibrosis, hyperparathyroidism, hyperlipidemia, organic acidemias, hereditary pancreatitis, cystic fibrosis gene mutation
- Gallbladder—cholelithiasis, choledochal cyst
- Crohn disease
- Adhesions—congenital or secondary to previous abdominal surgery
- Visceral neuropathy or myopathy
- Superior mesenteric artery syndrome<sup>b</sup>

**Nongastrointestinal**

- Medications—anticholinergics, alcohol, idiosyncratic reaction (eg, codeine), chemotherapy, radiation therapy, overdose (especially aspirin or acetaminophen)
- Central nervous system—cyclic vomiting, migraine, anorexia nervosa, bulimia nervosa
- Motion sickness
- Metabolic—diabetic ketoacidosis, acute intermittent porphyria
- Pregnancy

<sup>a</sup>Sigurdsson L, Flores A, Putnam PE, et al. Postviral gastroparesis: presentation, treatment, and outcome. *J Pediatr*. 1997;131(5):751–754.

<sup>b</sup>Blank V, Werlin S. Superior mesenteric artery syndrome in children: a 20-year experience. *J Pediatr Gastroenterol Nutr*. 2006;42:522.

Cyclic vomiting is characterized by repeated episodes of intense nausea and vomiting with at least 3 attacks over a 6-month period or 5 attacks in any interval. Episodes last 1 hour to 10 days and are separated by at least a week. In an individual, the attacks are very stereotypic. Uncontrollable vomiting and retching (at least 4 times in an hour for at least 1 hour) are typical of an attack; but between episodes, children act well. Approximately 10% of these children have an identifiable gastrointestinal or extraintestinal (eg, renal, metabolic, or neurologic) disorder as the probable cause.

Abdominal migraine is a common cause of cyclic vomiting and is characterized by the paroxysmal onset of repetitious attacks often relieved with sleep. A strong family history of migraine is common.

Headache typical of migraine may rarely occur with episodes; abdominal pain is not unusual. Cyproheptadine, amitriptyline, topiramate, and propranolol are highly effective as prophylactic treatment for abdominal migraine; treatment success helps confirm the diagnosis. Abdominal epilepsy is a much less common cause of cyclic vomiting. A complete history of the sequence of events and electroencephalographic evaluation are useful in the evaluation, and anticonvulsants can be tried when this condition is suspected.

**EVALUATION**

Patient history is often the most helpful in narrowing the wide range of potential causes of vomiting. Evaluation of the gastrointestinal tract usually includes an

upper gastrointestinal contrast roentgenographic study. However, in an infant with persistent vomiting between 2 and 12 weeks of age, the first study is often an ultrasound of the abdomen for pyloric stenosis. Food allergy is in the differential diagnosis for gastroesophageal reflux in infants; therefore, with intractable reflux symptoms, it is reasonable to undertake a 2-week feeding trial with hypoallergenic formula. In the older infant or child with intractable reflux symptoms, eosinophilic esophagitis should be a consideration and requires endoscopic evaluation of the esophagus. Endoscopy is feasible in all children, even newborns, if performed by an experienced examiner using an appropriately sized instrument. Esophageal pH monitoring and impedance monitoring, esophageal biopsies, and gastroesophageal scintiscan are all useful in establishing a diagnosis of gastroesophageal reflux. Endoscopically placed wireless esophageal pH capsule monitoring can be performed in children older than 2 to 3 years and is generally well tolerated.

If brain tumor is a consideration, magnetic resonance imaging is more sensitive than a computed tomography scan of the head. Further workup for metabolic or neurologic disease should be considered, as appropriate. With persistent vomiting, the physician should expect to see a metabolic alkalosis; metabolic acidosis raises concerns about an underlying metabolic disorder or drug intoxication. Metabolic workup often includes a urine test for organic acids and amino acids, urinalysis for ketones as well as serum glucose, blood urea nitrogen, electrolytes, lactate, ammonia, and total carnitine and acylcarnitine levels. In a postpubertal girl, pregnancy must always be considered in the differential diagnosis of vomiting.

When a midgut volvulus is suspected in a newborn or older child, a plain radiograph of the abdomen may show a paucity of gas distal to the upper small intestine; however, the radiograph may not be helpful. An upper gastrointestinal contrast radiographic study should be done at once, with the controlled introduction of barium through a nasogastric tube after gastric aspiration. A barium enema investigation of cecal position is a less reliable study when evaluating a patient for malrotation because of the lack of complete correlation of developmental rotation of the cecum with that of the duodenum.

## COMPLICATIONS

The most significant complications of vomiting include dehydration and electrolyte imbalance, especially when the vomiting is persistent, as well as aspiration pneumonia, hemorrhage from prolapse gastropathy (a hemorrhagic area on the posterior wall of the proximal stomach), or, less commonly, a tear at the gastroesophageal junction (Mallory-Weiss syndrome) and rupture of the esophagus (very uncommon in children). Feeding refusal may follow persistent vomiting, especially in infants.

## TREATMENT

Acute intercurrent vomiting without serious underlying disease or significant dehydration should be treated by administering clear liquids by mouth (eg, in

acute gastroenteritis or otitis media). The usually advisable course is to start with a period of 4 to 6 hours without oral intake and then begin with frequent small quantities of clear liquids (1 teaspoonful every few minutes for infants) and gradually increase the volume and extension of the period between oral fluids. If vomiting is associated with diarrhea and dehydration, then oral rehydration solution is indicated. Carbonated beverages may increase vomiting. Fluids of high osmolality, long-chain triglycerides, and anticholinergic drugs all tend to slow gastric emptying and should be avoided.

The drugs used most commonly, when necessary, for symptomatic improvement of acute or persistent vomiting are ondansetron and promethazine. If emesis interferes with administration, ondansetron is available as an oral disintegrating tablet and promethazine as a suppository. Ondansetron is generally preferred because of fewer side effects. When indicated, ondansetron has been used in children older than 6 months for vomiting associated with gastroenteritis, reducing the frequency of emesis and need for intravenous hydration.

For chemotherapy-induced vomiting, 5-HT<sub>3</sub> receptor antagonists (especially ondansetron and granisetron) have been effective. Dexamethasone and NK<sub>1</sub> receptor antagonists (aprepitant) can be added when necessary. Metoclopramide is added occasionally, but less frequently than in the past. Unfortunately, these treatments are not as effective in controlling nausea as vomiting.

H<sub>1</sub> receptor antagonists (including diphenhydramine, dimenhydrinate, meclizine, and promethazine) and muscarinic cholinergic receptor antagonists (eg, scopolamine) prevent motion sickness. Low-dose erythromycin or metoclopramide has been used to treat poor gastric emptying when there is not a mechanical obstruction (eg, postviral gastroparesis).

Patients should be monitored for signs of dehydration. For persistent vomiting with feeding, a nasoduodenal infusion may be useful. Significant vomiting that requires intravenous fluid therapy is usually associated with hypochloremic alkalosis with secondary hypokalemia. Intravenous fluids should repair the deficits.

Management of gastroesophageal reflux must be individualized. The extent of treatment necessary depends on the volume of emesis and the presence of complications of reflux. Medical management for infants includes thickening feedings with cereal (a standard concentration is 1 tablespoonful of cereal for each 1 to 2 ounces of formula) or the use of commercial antiregurgitant formula, which can reduce the amount of overt emesis but not reflux into the esophagus. Although prone positioning of young infants reduces reflux, this should only be done when the infant is observed and awake because the risk for sudden infant death syndrome is increased in this position. Prone positioning may be useful after 1 year of age. Left lateral decubitus positioning is discouraged for sleeping infants as well because these infants may become prone during sleep. Elevating the head of the bed remains standard therapy for older children and adults. Older children may benefit from avoiding snacks or liquids after dinner and agents that exacerbate esophagitis (alcohol, caffeine, and smoking).

Medications are commonly used to decrease exposure of the esophageal mucosa to acid (antacids, H<sub>1</sub> receptor blockers, or proton pump inhibitors). Attempts to improve lower esophageal function and gastric emptying (eg, metoclopramide) have been less successful because of unacceptable medication side effects. Baclofen has been suggested as an agent to reduce the frequency of inappropriate relaxations of the lower esophageal sphincter, but there is still limited experience in children. A slurry of sucralfate (a cytoprotective agent) is used occasionally for management of acid damage to the esophagus. When a child has severe gastroesophageal reflux, medical management may be unsatisfactory. In this case, antireflux surgery (fundoplication) should be considered. In this group of children, the results of surgery are generally good when performed by an experienced surgeon, and the benefits can be long lasting. In children who have psychomotor retardation and gastroesophageal reflux, antireflux surgery may not eliminate respiratory symptoms because other factors, such as swallowing dysfunction, may contribute to these findings. Among children undergoing a Nissen fundoplication, the risk for postoperative complication may be in the range of 10% to 30% and underscores the need for careful patient selection for this operation.

### WHEN TO REFER

- Persistent vomiting
- Recurrent episodes of vomiting
- Vomiting associated with a significant underlying process (eg, surgical abdomen, neurologic problem)

### WHEN TO ADMIT

- Intractable vomiting with dehydration
- Vomiting in association with symptoms or signs of an acute abdominal process (eg, acute appendicitis, pancreatitis, cholecystitis)
- Vomiting in association with symptoms or signs of raised intracranial pressure

## Chapter 207 WEIGHT LOSS

Diane E. Bloomfield, MD; Elaine A. Dinolfo, MD, MS

Weight loss in an infant, child, or adolescent is an uncommon but highly significant event. As the chief complaint or as an incidental finding, weight loss should be evaluated and followed up carefully by serial measurements and documentation on standardized growth charts. Revised growth charts from the Centers for Disease Control and Prevention released in January 2002 represent a broad cross-section of children in the United States. The charts are based on 5 large national samples that included breastfed and formula-fed infants, adolescents to the 20th birthday, and a racially and ethnically diverse population. With emphasis on growth parameters and body mass index, the charts include both 3rd and 97th percentile curves, which may be valuable in assessing weight loss. The definition of significant weight loss varies by the child's age and includes acute and chronic causes.

Subjective impressions of weight loss should be verified objectively before an evaluation is undertaken. True weight loss, however, may sometimes be difficult to differentiate from factitious weight loss, even when weights are documented in the medical record. Errors in weighing children occur at frequencies ranging from 5% to 20% of all children weighed, most commonly from faulty equipment or poor technique, such as weighing with the child's clothes on.

### NEWBORNS AND YOUNG INFANTS

The full-term healthy newborn may lose 5% to 10% of birth weight in the first few days but should regain

this weight by day 10 of life. A loss of more than 10% to 12% of birth weight is uncommon and should be investigated. The assessment should include overall health of the infant, adequacy of oral intake, and calculation of fluid losses from vomitus, urine, or stool. In general, an infant should gain 25 to 30 g each day in the first 3 months of life.

The most common reason for the breastfed infant to lose more weight than expected or to fail to regain the lost weight by 10 days of age is inadequate intake at the breast. The parental perception that the mother's milk supply is insufficient or less nutritious than formula should not be reinforced. Inadequate weight gain occurs because of infrequent or short feedings, failure of the let-down reflex, or improper positioning of the infant for an effective suck. The infant may appear well or may have signs of significant dehydration. Mothers may report that the infant has less than 6 urinations a day and few bowel movements. Lack of bowel movements in the breastfed newborn is a key indicator of inadequate caloric intake.

The breastfeeding mother should be observed nursing, if possible, and specific evidence of a let-down reflex should be sought, including uterine cramps, milk dripping or spraying from the opposite breast, and a pins-and-needles sensation in the breast at the beginning of each nursing. The infant should be observed latching onto the breast correctly, and loud swallowing or occasional choking may be noted at the beginning of the feeding. The mother's motivation to breastfeed and her positive or negative feelings about the experience should be discussed. Encouragement and support should be given for continuation of nursing, including specific suggestions for maternal rest, nutrition, and nursing frequency (every 2–3 hours in the day) to build up the milk supply. Formula or other fluids should not be recommended unless serious concerns exist about the infant's well-being. Recommending discontinuing breastfeeding prematurely is inappropriate for the physician. An appropriate weight gain in the following few days provides evidence that the infant is well and confirms the diagnosis of initial underfeeding. Infants who fail to thrive while breastfeeding require more intensive nutritional rehabilitation while still preserving breastfeeding.

The formula-fed newborn rarely loses more than 5% of birth weight in the first few days, inasmuch as complete nutrition is available beginning a few hours after birth. Weighing less than birth weight at the age of 10 days is unusual for a formula-fed infant, and such an infant should be evaluated thoroughly. An error in feeding caused by maternal inexperience is the usual explanation, with poor caloric intake most often from either inadequate feedings or faulty preparation of formula. If such is not the case, then a thorough search for an organic problem and an evaluation of family dynamics, support mechanisms, and adjustment to the newborn are indicated. In rare instances, a newborn will lose weight as a result of inadequate intake for other reasons, such as infection, congenital heart disease, inborn error of metabolism, somnolence from maternal medications or substance abuse,

or poor suck resulting from a craniofacial or central nervous system (CNS) abnormality. Weight loss can also result from excessive fluid loss, such as vomiting associated with congenital gastrointestinal malformations (duodenal atresia, annular pancreas, volvulus), or from diarrhea or polyuria (diabetes insipidus, renal disease) (Box 207-1).

## OLDER INFANTS, PRESCHOOLERS, AND SCHOOL-AGED CHILDREN

The most common reason for weight loss in older infants and toddlers is fluid loss as a result of fever, vomiting, and diarrhea. The loss of weight typically amounts to less than 10% of premorbid body weight and is usually reversed after a few hours of oral or intravenous fluid replacement.

Infants who lose more than 10% of their body weight from excessive vomiting require further investigation for pyloric stenosis and malrotation as well as for tumors of the CNS, which may cause vomiting, anorexia, and cachexia.

Weight loss may also accompany any severe febrile illness, such as pneumonia, pyelonephritis, septic arthritis, osteomyelitis, or meningitis, as well as less severe illnesses, such as stomatitis and pharyngitis. Resolution of the infection is often followed by a period of catch-up growth and weight gain.

Inefficient use of caloric intake can also result in weight loss. Cystic fibrosis, the most common disease in which malabsorption occurs in childhood, may appear in infancy as poor weight gain or actual weight loss. Intestinal disorders such as celiac disease, Hirschsprung disease, inflammatory bowel disease, and other causes of malabsorption will also lead to weight loss or poor weight gain.

Weight loss from chronic diarrhea may be caused by a variety of infectious diseases, including HIV infection. A diagnosis of tuberculosis should also be considered in every child who has lost weight.

Children with new-onset insulin-dependent diabetes mellitus commonly lose weight (often 10% or more of body weight) despite polyphagia and polydipsia. Hyperthyroidism is another endocrine disorder that may lead to weight loss in childhood.

Malignancies, including leukemia, lymphoma, and neuroblastoma, may have weight loss as part of their presenting picture or even as their initial symptom.

Poverty remains the greatest single risk factor for failure to thrive in the United States; however, other psychosocial factors (poor parent-child interaction, depression, rumination) often underlie an infant's or a child's poor growth and development. Actual weight loss is much less common in this setting than a slow-down or cessation of weight gain and linear growth. Psychosocial dysfunction that results in a child's weight loss requires a prompt and thorough evaluation. Eating disorders have been described in prepubertal children as young as 7 years. In addition, as reported by the Agency for Health Care Research and Quality, the largest increase in the rate of hospitalizations for eating disorders occurred in children younger than 12 years.

**BOX 207-1 Differential Diagnosis of Weight Loss by Age Group****NEWBORNS AND YOUNG INFANTS**

- Difficulties in establishing breastfeeding
- Inappropriate dilution or choice of formula
- Inadequate intake
- Infection
- Metabolic abnormality
- Craniofacial abnormalities
- CNS dysfunction
- Somnolence from maternal medications/substance abuse
- Congenital heart disease
- Maternal depression/inexperience/lack of knowledge
- Excessive losses secondary to vomiting or diarrhea
- Vomiting because of gastrointestinal malformations (duodenal atresia, others)
- Polyuria (diabetes insipidus, renal disease)
- Diarrhea

**OLDER INFANTS, PRESCHOOLERS, AND SCHOOL-AGED CHILDREN**

- Pyloric stenosis
- Gastroesophageal reflux
- CNS tumors
- Vomiting
- Diarrhea
- Fever and infection
- Diabetes mellitus
- Excessive activity
- Inadequate intake

- Fever and infection
- Tuberculosis
- Surgery
- Medication effect (loss of appetite)
- Malignancy
- Congenital heart disease
- Malabsorption syndromes
- Inflammatory bowel disease
- Immunodeficiency disorders, especially HIV infection
- Psychosocial dysfunction
- Poverty
- Neglect; nonorganic failure to thrive
- Parental depression
- Childhood depression
- Rumination
- Childhood eating disorder

**ADOLESCENTS**

- Dieting behavior
- Adolescent eating disorders
- Anorexia nervosa
- Bulimia nervosa
- Other eating disorders
- Psychiatric affective disorders, especially depression
- Malignancy
- Inflammatory bowel disease
- Diabetes mellitus
- Hyperthyroidism
- Tuberculosis

CNS, central nervous system; HIV, human immunodeficiency virus.

**ADOLESCENTS**

Monitoring the adolescent growth curve, including body mass index, is crucial to the recognition of weight loss and should be a part of every encounter. The prevalence of obesity in children and adolescents has increased in the past decade, leading to an unhealthy emphasis on dieting and weight loss among children and adolescents. Planned dieting must be distinguished from an eating disorder such as anorexia nervosa or bulimia nervosa. The 2010 American Academy of Pediatrics policy statement regarding the identification and management of eating disorders estimates that 0.5% of female adolescents have anorexia nervosa, that 1% to 2% meet criteria for bulimia nervosa, and that up to 5% to 10% of all cases of eating disorders occur in boys. The American Psychiatric Association acknowledges that a large number of patients do not meet the strict diagnostic criteria for anorexia nervosa and bulimia nervosa; in the 2013 revision of the *Diagnostic and Statistical Manual of Mental Disorders*, these individuals are labeled OSFED (Other Specified Feeding or Eating Disorder). The

prevalence of this diagnosis is estimated to be between 0.8% and 14%; these adolescents remain at risk for both physical and psychological complications from their altered eating habits.

Anorexia nervosa should be suspected when the adolescent is unwilling or unable to maintain body weight over a minimally normal weight for age and height and when attitudes and behaviors about eating or body image are distorted. The anorectic female adolescent may experience amenorrhea associated with emaciation and overactivity. The patient may demonstrate clinical signs of malnutrition such as hypothyroidism, bradycardia, hypothermia, and growth of lanugo-like hair on the body and extremities. Nutritional rehabilitation and psychiatric treatment are indicated. Adolescents who have bulimia indulge in binge eating, followed by self-induced vomiting, self-starvation, overactivity, or the use of cathartics or diuretics to reduce weight. These behaviors are practiced in secret, and the adolescent often denies them. An elevated serum bicarbonate level, hypokalemia, or high urine pH may provide evidence of chronic

vomiting. The patient is often depressed and self-deprecating and may seek medical aid when the eating-vomiting pattern becomes compulsive and out of the patient's control. Psychiatric evaluation and intervention are indicated.

Young adults who participate in sports may follow unhealthy weight-control practices to seek advantage in their athletic activities, including food restriction, vomiting, overexercise, diet pills, stimulants, insulin, nicotine, and voluntary dehydration. For adolescents who participate in sports in which weight loss is a goal (eg, wrestling, gymnastics, ice skating, running, swimming, diving, dancing), a thorough dietary and supplement history should be elicited.

Although significant weight loss during adolescence can often be ascribed to eating disorders, other diagnoses must be considered. These conditions include psychiatric disturbances (especially affective disorders), CNS tumors (particularly those of the hypothalamus, sella turcica, or other midline areas), malignancies (especially lymphoma), or gastrointestinal problems such as inflammatory bowel disease or other malabsorption syndromes. Systemic disorders such as diabetes mellitus, hyperthyroidism, autoimmune disease, and renal disease may cause significant weight loss in adolescents. Infectious diseases such as HIV infection and tuberculosis should be considered when an adolescent patient reports weight loss.

## INITIAL EVALUATION OF A COMPLAINT OF WEIGHT LOSS

The following should be included in the initial evaluation (Table 207-1):

1. A complete history and thorough physical examination, with special attention to dietary intake, family functioning, and the patient's emotional well-being. The growth chart should be reviewed and updated.
2. A complete blood cell count (CBC) and erythrocyte sedimentation rate (ESR). The CBC screens for oncologic factors and provides an overview of the nutritional state. The ESR may be elevated in autoimmune diseases, chronic infections, certain malignancies, and inflammatory bowel disease; it may be abnormally low in anorexia nervosa.
3. Serum electrolyte and kidney function tests should be obtained to evaluate for dehydration, to reveal evidence of pernicious or self-induced vomiting, and to rule out renal or adrenal disease.
4. Serum protein and albumin levels to assess liver function, to determine whether the weight loss represents malnutrition, and to rule out protein malabsorption. Reversal of the albumin-to-globulin ratio is often seen in autoimmune diseases and malignancies.
5. Tuberculosis skin test.
6. Stool for occult blood and tests of malabsorption to diagnose gastroenteritis, inflammatory bowel disease, and the various causes of malabsorption. The serum carotene level may be low in infancy and in malabsorptive conditions but is often elevated in anorexia nervosa.

**Table 207-1**

## Laboratory Studies Helpful in Weight Loss

SUGGESTED STUDIES	SUGGESTED DIAGNOSES
Complete blood cell count, smear	Anemia Infection Nutritional deficiencies Malabsorptive syndromes Malignancy
ESR	Autoimmune disease Infection Inflammatory bowel disease Malignancy Anorexia nervosa (very low ESR)
Serum electrolytes, kidney function tests	Dehydration Vomiting, self-induced or pernicious Renal dysfunction Adrenal disorders Metabolic disorder (with acidosis) Autoimmune disease
Serum protein and albumin levels	Liver dysfunction Malignancy Malnutrition Protein malabsorption Protein-losing enteropathy
Tuberculosis skin test	Tuberculosis
Stool for occult blood	Gastroenteritis Inflammatory bowel disease Enteropathies
Serum carotene; specific tests of malabsorption	Malabsorption syndromes Cystic fibrosis Anorexia nervosa (high carotene)
Urinalysis, including specific gravity; urine culture	Diabetes mellitus Diabetes insipidus Dehydration Urinary tract infection Renal disease Adolescent eating disorder (high pH)

ESR, erythrocyte sedimentation rate.

7. Urinalysis and urine culture to rule out diabetes mellitus, diabetes insipidus, dehydration, urinary tract infection, and renal disease. The urine pH may be high (>8) in adolescents who have eating disorders, particularly when vomiting occurs.

## WHEN TO REFER

Evidence or suspicion of

- Malignancy
- Endocrinopathy (thyroid, adrenal, pituitary)
- Gastrointestinal disorder (eg, gastroesophageal reflux; malabsorption, including cystic fibrosis; inflammatory bowel disease)
- Pancreatitis
- Heart disease
- Renal disease
- Pulmonary disease

- Rheumatologic condition
- CNS abnormality
- Metabolic disorder
- Surgical abdominal problem (eg, pyloric stenosis, Hirschsprung disease, volvulus)
- Immunodeficiency
- Unusual infection
- Psychiatric diagnosis in child or caretaker
- Anorexia nervosa or bulimia nervosa in the child or adolescent

### WHEN TO ADMIT

A newborn, when

- Weight loss cannot be managed as outpatient
- Weight loss of more than 12% to 15% of birth weight
- Excessive fluid loss (vomiting, diarrhea, polyuria)
- Evidence of infant hypernatremic dehydration
- Suspicion of infection, metabolic abnormality, congenital heart disease, other conditions requiring evaluation
- Extreme passivity of the infant, which may require tube feeding
- Need for intensive maternal education and support

At any age, when

- Weight loss is excessive (more than 5%–10% of previous weight)
- Excessive fluid loss from vomiting or diarrhea
- New-onset diabetes mellitus (usually)
- Evidence of severe febrile illness (pneumonia, pyelonephritis, osteomyelitis, meningitis, septic arthritis, others)
- Evidence of dehydration
- Physiologic instability
- Severe bradycardia
- Hypotension
- Hypothermia
- Orthostatic changes
- Electrolyte abnormalities (eg, hypernatremia, hypokalemia)
- Evidence of significant psychosocial dysfunction

An adolescent, when

- Eating disorder cannot be managed as outpatient
- Severe malnutrition, with weight
- Evidence of dehydration or electrolyte abnormalities
- Physiologic instability
- Acute food refusal
- Uncontrollable binge eating and purging
- Acute medical complication of malnutrition (syncope, seizures, cardiac failure, pancreatitis)
- Suicidal intent or ideation, or psychosis

## Chapter 208

# WHEEZING

Alfin G. Vicencio, MD; Joshua P. Needleman, MD

### DEFINITION

Wheezing, a continuous musical sound that represents turbulent intrathoracic airflow, is usually most prominent during expiration, but it may also be present in inspiration. A history of wheezing reported by family members, however, is insensitive and nonspecific because untrained observers without appropriate equipment often mistake many other respiratory sounds for wheezing.

During the normal respiratory cycle, rhythmic expansion and contraction of the thorax lead to dynamic changes in thoracic pressures, allowing air to flow into and out of the lungs (Figure 208-1). On inspiration, the thoracic cavity expands, resulting in negative intrathoracic and airway pressures (relative to atmospheric pressure), allowing air to flow into the lungs. Extrathoracic airway obstruction, signaled by stridor (see Chapter 197, Stridor), is most likely to cause turbulent airflow during this phase of the respiratory cycle (see Figure 208-1, A). Expiration is accomplished by contracting the volume of the thoracic cavity, creating positive pressure in the thorax, which is

transmitted to the intrathoracic airways. Thus, during expiration, the intrathoracic airways are more prone to obstruction leading to turbulent airflow (see Figure 208-1, B). It should be noted that obstruction occurring at the thoracic inlet or severe fixed obstruction at any level of the airway may cause abnormal noises that are not limited to one phase of the respiratory cycle, including biphasic wheezing.

Although wheezing is most commonly associated with the distal airway obstruction seen in viral bronchiolitis or asthma, several other diseases can cause small airway obstruction and can be indistinguishable on physical examination. Similarly, abnormalities causing obstruction of the mid or distal trachea or main-stem bronchi, both of which reside within the thorax, can cause wheezing. Thus, although bronchiolitis and asthma will certainly account for most children who wheeze, the general pediatrician should be prepared to initiate a more extensive evaluation for the wheezing child, particularly for patients with unusual presentations or if conventional treatment yields less than optimal results.

### DIFFERENTIAL DIAGNOSIS

The differential diagnosis of wheezing is extensive and includes any process that can cause obstruction of intrathoracic airways. Because the intrathoracic airways include large centrally located airways and smaller peripheral bronchioles, determining the level of obstruction is often helpful before generating a list of differential diagnoses (see Evaluation).

**Figure 208-1** The respiratory cycle and related airway changes. **A**, During inspiration, negative intrathoracic pressures generated by thoracic expansion are likely to cause obstruction in the extrathoracic airway (red arrow) leading to stridor. **B**, During expiration, positive intrathoracic pressures generated by thoracic compression are likely to cause obstruction in the intrathoracic airways, including the mid and distal trachea, main-stem bronchi, and small bronchioles, leading to wheeze.

Viral bronchiolitis and asthma account for most wheezing localized to the small peripheral airways. A major challenge in evaluating the wheezing child is determining when the wheeze is not caused by asthma or bronchiolitis, but rather by a different process requiring different diagnostic approaches and alternate treatment strategies. For example, cystic fibrosis, a severe genetic disease causing progressive small airway obstruction, can be mistaken for poorly controlled asthma. Similarly, early congestive heart failure can produce intractable wheezing from peribronchial edema. Pulmonary hemosiderosis, a rare disorder, can cause anemia and recurrent wheezing because blood irritates the peripheral airways. In a similar manner, gastroesophageal reflux and recurrent aspiration can also result in persistent or recurrent wheezing and may also complicate large airway abnormalities.

Distinguishing large airway obstruction (ie, trachea or main-stem bronchi) from small airway obstruction (ie, asthma) is difficult because both can cause expiratory wheeze. In addition, a variety of abnormalities can cause large airway obstruction, further complicating evaluation and diagnosis. Dynamic lesions of the large airways such as tracheomalacia or bronchomalacia are fairly common causes of congenital wheezing and can also be associated with gastroesophageal reflux, tracheoesophageal fistula, or prolonged mechanical ventilation in premature infants. External compression of large airways can be seen with vascular abnormalities (rings and slings), mediastinal masses, or infectious agents, most notably lymphobronchial tuberculosis or histoplasmosis.

For any child with a sudden onset of wheezing or a history of choking, the possibility of a foreign body should be of particular concern. Importantly, many patients with foreign body aspiration will not have an obvious history of choking, and as such one should always maintain a suspicion for this possibility, even in a child whose wheezing has been present for days or weeks. Finally, intrinsic airway abnormalities, including complete tracheal rings and webs, and acquired obstructions, such as tracheal stenosis or granulation tissue, can cause intractable wheezing.

## EVALUATION

### History

A major challenge in evaluating the wheezing child is to determine when a wheeze is not caused by viral bronchiolitis or asthma. Wheezing caused by viral bronchiolitis is usually preceded by upper respiratory symptoms and fever, often worsens within the first few days of onset, and tends to improve slowly thereafter. Asthma exacerbations are often initiated by vigorous activity, changes in weather, upper respiratory infection, or exposure to a triggering allergen. Such exacerbations typically respond well to inhaled  $\beta$ -agonist therapy with or without systemic corticosteroids. Persistent or recurrent episodes of wheezing that do not fit these profiles and have a family history that supports the diagnosis of asthma should be evaluated more thoroughly.

A detailed and focused history can often provide clues to an accurate diagnosis. Wheezing that appears

at birth or soon afterward should prompt an evaluation for congenital airway abnormalities such as tracheomalacia, complete rings, or vascular abnormalities or compression. Wheezing after a recent surgical procedure or intubation suggests acquired obstruction, whereas abrupt onset of wheezing accompanied by a history of choking should prompt an evaluation for aspiration of a foreign body. Other clues that suggest underlying illnesses or abnormalities include constant wheezing, failure to thrive, hemoptysis, difficulty swallowing, frequent vomiting, positional wheezing, worsening with agitation or crying, and poor response to conventional therapy.

### Physical Examination

Location of airway obstruction can often be determined by thorough physical examination and can direct the ensuing workup. Unilateral wheezing, most often associated with aspiration of a foreign body, can also accompany unilateral bronchial compression or stenosis and should be evaluated thoroughly. In addition to determining whether the wheezing is bilateral or unilateral, detailed assessment of the auditory characteristics can help determine whether the obstruction is central or peripheral. For example, wheezing that varies in pitch and can be heard throughout the chest (musical, heterophonous) typically represents small airway obstruction. In contrast, central airway obstruction tends to sound more even in pitch (monophonic, homophonous) and can often be heard best in central locations such as the sternal notch, although this may be unreliable in a small infant. In addition, large airway obstruction is more likely than small to be heard throughout the entire expiratory phase.

In addition to the auditory composition of a wheeze, positional characteristics can help determine cause. For example, wheezing caused by a dynamic lesion such as tracheomalacia is often worse when a patient is supine. Mediastinal structures such as the heart and the great vessels, which lie immediately anterior to the trachea, tend to fall posteriorly in the supine position and can be obstructive. In contrast, these structures tend to fall anteriorly when the patient is prone, relieving pressure on the airway and improving the wheeze. Wheezing caused by small airway obstruction or fixed compression of a large airway does not typically change with position.

### Objective Testing

Although a detailed history and physical examination can help the physician narrow the list of potential diagnoses, additional testing is often helpful and may guide therapy. Information obtained through the history and physical examination should guide further evaluation. Table 208-1 highlights the features of some common abnormalities that cause wheezing.

Laboratory testing may be indicated to diagnose specific clinical entities. For example, a sweat test is required if cystic fibrosis is suspected, and viral studies can identify respiratory syncytial virus or influenza as a cause of small airway wheezing in an infant with upper respiratory symptoms.

Pulmonary function testing can help characterize a wheeze objectively in patients older than 5 or 6 years.

**Table 208-1** Causes of Recurrent or Persistent Wheeze

	FEATURES	OBJECTIVE FINDINGS
Asthma	Worse with exercise or respiratory infections Responds to bronchodilators Responds to steroids Family history of atopy	Reversible obstruction on PFTs Homophonous wheeze Positive bronchoprovocation
Tracheomalacia	Worse with activity or agitation Poor response to bronchodilators Poor response to steroids	Homophonous wheeze Airway collapse on fluoroscopy Collapsible trachea on bronchoscopy
Bronchomalacia	Worse with activity or agitation Poor response to bronchodilators Poor response to steroids	Heterophonous wheeze Airway collapse on fluoroscopy Collapsible bronchus on bronchoscopy
Foreign body	Sudden onset May have a history of choking	Asymmetrical breath sounds Asymmetrical hyperinflation or collapse on radiograph
Heart failure or pulmonary edema	Poor response to bronchodilators Poor growth	Hepatomegaly Radiograph with increased fluid Responds to diuresis
Bronchiolitis	Infant: URI symptoms	Positive viral studies
Vocal cord dysfunction	Poor response to all therapies Severe distress reported	PFTs: normal or with abnormal inspiratory loop Laryngoscopy: vocal cord adduction during inspiration
Cystic fibrosis	Poor growth, GI symptoms Recurrent pneumonia	Positive sweat test
Gastroesophageal reflux and aspiration	Variable response to bronchodilators Often worse after meals	Positive reflux evaluation (upper GI, nuclear scan, or pH probe)
Vascular compression	Central wheeze No bronchodilator response	Indentation on esophagram Anatomy demonstrated on thoracic MRI
Large airway abnormality (stenosis, complete rings, compression)	No response to therapy Worse with activity Stridor noted at times	Flattened or square flow-volume loop Obstruction visible on imaging or bronchoscopy

GI, gastrointestinal; MRI, magnetic resonance imaging; PFT, pulmonary function test; URI, upper respiratory infection.

**Figure 208-2** Pulmonary function test demonstrating small airway obstruction. Small airway obstruction, such as that seen in asthma, has a distinctive scooped appearance on spirometry. Normalization of the flow loop after bronchodilator treatment strongly suggests asthma as the underlying cause of recurrent wheezing.

The expiratory loop shown in Figure 208-2 demonstrates small airway obstruction that improves after bronchodilator therapy, suggesting asthma as the underlying cause of recurrent wheezing. In contrast, small airway obstruction that does not demonstrate

**Figure 208-3** Pulmonary function test demonstrating large airway fixed obstruction. Fixed obstruction of a large airway by compression or stenosis will result in a characteristic flat expiratory loop on spirometry. No change will occur after administering bronchodilator.

reversibility after bronchodilator therapy may require additional workup; several disease processes, including cystic fibrosis, congestive heart failure, and obliterative bronchiolitis, can cause fixed small airway obstruction. Similarly, expiratory loops suggesting fixed large airway obstruction (Figure 208-3) may require further evaluation for stenosis, rings, or compression.

**Figure 208-4** Foreign-body aspiration. **A**, Chest radiograph demonstrates mild hyperaeration of the right lung and mild flattening of the right hemidiaphragm on anteroposterior view. **B**, On left lateral decubitus view, the hyperaeration of the right lung is accentuated. **C**, On right lateral decubitus view, the heart does not shift with gravity, and the right lung remains well inflated. A peanut was found in the right main-stem bronchus during bronchoscopy.

Inspiration

Expiration

**Figure 208-5** Airway fluoroscopy. Airway fluoroscopy demonstrates a normal trachea during inspiration (arrows). On expiration, severe collapse of the trachea is demonstrated, indicating tracheomalacia.

Radiographic studies can be helpful when evaluating a patient with persistent or recurrent wheeze, particularly when asthma or viral bronchiolitis is not likely the cause. Chest radiography can detect thoracic masses that cause obstruction of airways. In addition, chest radiography with decubitus films or inspiratory and expiratory views can be helpful in diagnosing foreign-body aspiration (Figure 208-4). If history and physical examination suggest tracheobronchomalacia as an underlying diagnosis, then airway fluoroscopy (Figure 208-5)

can confirm the diagnosis and help quantify the severity. An esophagram or upper gastrointestinal series is useful if a vascular abnormality is suspected. However, although a vascular abnormality can be easily identified by an esophageal notch in an esophagram, a computed tomographic scan with contrast (Figure 208-6) or magnetic resonance image is ultimately required to determine the exact anatomic variant, which may include a double aortic arch, a right aortic arch with aberrant left subclavian, or a pulmonary artery sling.

**Figure 208-6** Esophagram and computed tomographic scan. **A**, Esophagram demonstrates a posterior indentation suggestive of a vascular ring. **B**, Computed tomographic scan of the chest confirms the presence of a double aortic arch

**Figure 208-7** Images from fiberoptic bronchoscopy. Fiberoptic bronchoscopy demonstrates normal tracheal caliber during inspiration. During expiration, the distal trachea collapses, consistent with tracheomalacia.

Direct visualization of the airway via flexible bronchoscopy is increasingly used to better characterize dynamic lesions such as tracheobronchomalacia (Figure 208-7). Intrinsic airway abnormalities, such as complete cartilaginous rings, often require bronchoscopy to make a diagnosis (Figure 208-8). Improved radiologic techniques, such as 3-dimensional airway reconstruction, may be useful, although the high radiation dose should limit their use (Figure 208-9). Furthermore, rigid bronchoscopy can be useful in both diagnosis and treatment of tracheal stenosis (Figure 208-10). Bronchoscopy can help assess the severity of airway compression by a thoracic mass and confirm patency after resection (Figure 208-11).

## MANAGEMENT

Most patients with wheezing have viral bronchiolitis and asthma and should be managed accordingly. Although some children with viral bronchiolitis or asthma require hospitalization for severe respiratory

distress, hypoxemia, poor feeding, or dehydration, the general pediatrician can care for most children in an outpatient setting. An important point to note is that, currently, no evidence exists to support the regular use of  $\beta$ -agonist therapy in viral bronchiolitis. Hypertonic 3% saline has recently been used as adjunctive therapy for hospitalized patients with bronchiolitis. Hospital admission or referral to a subspecialty physician may be indicated for chronic wheezing associated with failure to thrive, which can be a sign of a significant underlying disease. Similarly, an unusual history or physical examination should prompt more detailed evaluation and may require alternate treatment regimens, depending on the cause. In general, the pediatrician evaluating the child with wheeze should be aware of the various clinical entities that can produce wheezing, be able to recognize by history or physical examination patients who require further workup, initiate simple diagnostic tests, and refer to appropriate subspecialty physicians children with unusual presentations or poor response to conventional therapies.

#### WHEN TO REFER

- Persistent or recurrent wheezing in an infant younger than 1 year
- Apparent paradoxical response to bronchodilators
- Poor weight gain or growth associated with chronic or recurrent wheezing
- Repeated hospitalization or multiple courses of oral corticosteroids
- Persistent asymmetric wheezing

**Figure 208-11** Images from fiberoptic bronchoscopy. Complete obstruction of the distal left main-stem bronchus secondary to a mediastinal mass. Immediately after resection of the mass, the segmental branch points of the left lung are easily identified.

### WHEN TO ADMIT

- Respiratory distress unresponsive to therapy
- Hypoxemia
- Tachypnea interfering with ability to eat or drink
- Altered mental status or signs of fatigue

## Chapter 209

### ACNE

Catherine Chen, MD; Judith V. Williams, MD

Acne is so prevalent in adolescents and young adults that some people consider it a physiologic event. This perspective does not take into account the effect of acne on the patient, and it may preclude therapeutic intervention. Acne is a treatable disease that deserves medical attention.

### ETIOLOGY

#### Hormones

Acne is a disease of the pilosebaceous unit. Androgens stimulate the sebaceous glands, which enlarge and increase their production of sebum. Before puberty, the responsible androgens are of adrenal origin. After puberty, gonadal androgens further stimulate the sebaceous glands. Patients who have acne may have normal levels of circulating testosterone; therefore, tissue androgen metabolism may be an important factor in the pathogenesis of acne. One of the major organs for androgen metabolism is the skin, where the enzyme 5- $\alpha$ -reductase metabolizes testosterone to dihydrotestosterone, which has significantly increased potent activity at the tissue level. 5- $\alpha$ -reductase may be more active in the skin of patients with acne than those without, increasing androgenic stimulation of the sebaceous glands and ultimately causing acne. Increased sebaceous gland activity is necessary for acne to develop; alone, it is insufficient to cause disease.

#### Follicular Obstruction

If sebum is allowed to drain freely to the surface, the surface skin then becomes oily, but acne does not develop. Acne can develop only if the outlet of the follicular canal is obstructed, which occurs when adherent, keratinized cells within the canal accumulate and form an impaction that blocks the flow of sebum (Figure 209-1). Production of keratinized cells within the lining of the follicular canal is normal, but accumulation and subsequent impaction are not. This follicular obstruction, which may also be influenced by androgens, is a prerequisite for the development of acne.

#### Bacteria

Sebum and keratinous debris accumulate proximal to the follicular outlet obstruction. This accumulation provides an attractive environment for the growth of anaerobic bacteria, particularly *Propionibacterium acnes*, which play a role in the pathogenesis of inflammatory acne. Several factors may be involved in causing the inflammation. One theory suggests that the lipase enzymes elaborated by *P acnes* hydrolyze sebaceous lipids, releasing free fatty acids, which then cause irritation when the follicle ruptures. *P acnes* also

**Figure 209-1** Obstruction of the pilosebaceous unit in acne.

produce chemotactic factors that may attract inflammatory cells directly to a sebaceous follicle. Some evidence indicates that complement-mediated inflammation is directed against *P acnes* itself. Regardless of the mechanism of inflammation, little question remains as to the therapeutic benefit of antibiotics.

The events in the pathogenesis of acne include androgenic stimulation of sebaceous glands, which increases sebum production; keratinous impaction in the pilosebaceous canal, causing outlet obstruction; accumulation of sebaceous and keratinous debris behind the obstruction; and proliferation of *P acnes*, which alters this milieu in such a way as to contribute to the rupture of the dilated pilosebaceous unit, resulting in extravasation of its contents into the surrounding dermis and inflammatory acne lesions.

### CLINICAL FINDINGS

Not surprisingly, acne lesions have a predilection for skin that is rich in sebaceous glands. Accordingly, the face is the prevailing site, although acne is also often found on the chest and back. Occasionally a patient may have involvement of the conchal bowls of the ears. The lower portions of the trunk, buttocks, and thighs are involved much less frequently, and the distal extremities are always spared.

The disease process may begin at a surprisingly young age. In a study of premenarchal girls, 78% were found to have some acne. The same investigators found acne to be present in 100% of adolescent boys. Although the severity of the disease increases during

adolescence, acne is by no means confined to these years. For acne activity to continue into the third and fourth decades of life is not uncommon.

The pathogenic mechanisms previously described result in noninflamed open and closed comedones and inflammatory papules and pustules, as well as cystic acne in more severe cases. Cystic acne is made up of nodules greater than 5 mm in diameter and true cysts, which are compressible nodules under normal-seeming skin. These nodules and cysts can result in permanent acne scars.

The acne found in prepubertal children is predominantly noninflammatory and thus may easily be overlooked. The open comedo (blackhead) and closed comedo (whitehead) are lesions caused purely by obstruction of the pilosebaceous canal, with no accompanying inflammation. Inflammatory and comedonal acne is rare in young children between 1 and 7 years of age and suggests a possible hyperandrogenic condition, such as that associated with congenital adrenal hyperplasia or even a rare androgen-secreting tumor. Girls should be examined for virilization, and boys and girls should be checked for precocious puberty. Screening blood studies should include serum levels of testosterone, androstenedione, dehydroepiandrosterone sulfate (DHEA-S), and 17-hydroxyprogesterone. Bone age, follicle-stimulating hormone (FSH), and luteinizing hormone (LH) may also be assessed if appropriate. Referral to a pediatric endocrinologist should be considered if there is reason to suspect a hyperandrogenic basis for the acne.

## DIFFERENTIAL DIAGNOSIS

Diagnosing acne is rarely difficult. Usually, the condition can be diagnosed from across the room, although comedonal lesions may require closer inspection (Figure 209-2). Occasionally acne may be confused with flat warts, milia, or adenoma sebaceum; acne variants may occur.

### Flat Warts

Small, flesh-colored warts may be confused clinically with closed comedones. The question can usually be resolved with close inspection. A flat wart has a sharp, right-angled edge and a finely roughened surface; a closed comedo has a dome shape and a smooth surface. Flat warts also vary in size; closed comedones are uniformly small (Figure 209-3).

### Milia

Milia are small epidermal inclusion cysts that are sometimes confused with comedones and occasionally with inflammatory pustules, especially in infants who have neonatal acne.

### Adenoma Sebaceum

A misnamed disorder (the lesions are actually angiofibromas), adenoma sebaceum is one of the skin manifestations in tuberous sclerosis and also can be seen in multiple endocrine neoplasia. Clinically, the lesions appear as pink papules, which are occasionally confused with the lesions of acne. Adenoma sebaceum

**Figure 209-2** Closed comedones (whiteheads) appear as dome-shaped, flesh-colored papules that often are overlooked.

**Figure 209-3** Flat warts.

should be anticipated if the papules are clustered primarily in the center of the face, persistent, and resistant to acne therapy.

### Acne Rosacea

Acne rosacea is an acneiform eruption that can be distinguished from acne by a background blush of

**Figure 209-4** Rosacea.

erythema and telangiectasia and by the absence of comedones (Figure 209-4). In addition, rosacea occurs most often in middle-aged adults.

### Steroid Acne

Both systemic and topical steroids can induce acne. Acne from systemic steroids usually appears as numerous small, uniform-sized papules and pustules that have a predilection for the upper trunk. The hallmark of steroid-induced acne is a lack of comedones. The condition involutes slowly and spontaneously after the steroids are discontinued.

### Gram-Negative Folliculitis

Gram-negative organisms can occasionally produce a pustular folliculitis in patients being treated for acne with systemic antibiotics. This condition should be thought to exist in any patient whose disease flares up during therapy, especially if the flare-up produces numerous pustules. A bacterial culture with antibiotic sensitivity studies should be performed so that the diagnosis can be confirmed and the antibiotic therapy changed.

### Acne Conglobata

Acne conglobata is an unusually severe acne variant that may develop as a result of a sudden deterioration of existing active acne, or it may be a recurrence of acne that has been quiet for many years. It occurs most commonly in 18- to 30-year-old men. Lesions consist of comedones, cysts with foul-smelling seropurulent material, and burrowing and interconnecting abscesses, leaving irregular and disfiguring scars. At times, acne conglobata has been associated with systemic diseases such as hidradenitis suppurativa, pyoderma gangrenosum, renal amyloidosis, and musculoskeletal syndrome. The mainstay of treatment is isotretinoin.

### Acne Fulminans

Acne fulminans is a rare and severe form of acne, usually occurring in men and characterized by sudden

onset of painful acne nodules and, rarely, ulcerative lesions, as well as systemic symptoms, including fever, leukocytosis, polyarthritis, splenomegaly, erythema nodosum, and lytic bone lesions in long bones, clavicle, and sternum. Treatment involves a combination of systemic corticosteroids initially followed by isotretinoin. The prognosis is good, although residual scarring and disfigurement may persist.

## PSYCHOSOCIAL CONSIDERATIONS

Acne can be a devastating disease. In an ironic quirk, it occurs at a time of life when personal appearance is of prime concern and when self-consciousness is at its peak. Although some young people seem to be more affected psychologically by acne than others, no one is comfortable with it. Patients who have severe cystic acne may be socially ostracized. Regardless of the acne's severity, the condition is important to the patient who is seeking help and deserves serious attention. Patients are not impressed with advice that trivializes their disease and reassures them that they eventually will *outgrow it*. Fortunately, a wide array of medical therapies are available that can produce effective, gratifying results.

## MANAGEMENT

Five methods of treatment have proved effective for acne: topical comedolytic agents, topical and systemic antibiotics, systemic retinoids, and systemic hormonal therapy. The most traditional and effective treatment regimen is a combination of comedolytics and antibiotics.

### Comedolytics

Topical retinoids are the mainstay of acne treatment because they help disimpact the comedone—the keratinous plug in the follicular canal. They include tretinoin (Atralin, Retin-A, Retin-A Micro, Tretin-X), adapalene (Differin), and tazarotene (Tazorac, Fabior). They now are available in combination with other acne medications, such as tretinoin combined with clindamycin (Veltin, Ziana) and adapalene with benzoyl peroxide (Epiduo, Epiduo Forte), which can help with compliance. Other comedolytic agents include benzoyl peroxide (Benzac AC, Benzac W, Brevoxyl, Desquam-E, Desquam-X, Triaz, ZoDerm), salicylic acid, and sodium sulfacetamide (Klaron, Plexion, Rosula, Sebizon). Although topical retinoids have been traditionally viewed as having a primarily comedolytic effect, and more so than other topical medications, they also reduce inflammatory lesions and enhance penetration of other medications. In fact, consensus has now formed that, in most cases, topical retinoids (alone or in combination) should be used as first-line therapy for mild to moderate inflammatory acne in addition to comedonal acne. They are also preferred for maintenance therapy.

When a topical retinoid is used in a regimen with another topical “leave-on” agent, the patient should be instructed to apply the retinoid at bedtime and the other agent each morning. However, if the other agent is a wash, both agents can be applied in either the morning or evening, which may facilitate compliance. Topical comedolytics are available in a variety of

**Table 209-1**     **Tretinoin Preparations**

	MILDEST	MILD	MODERATE	STRONGER	STRONGEST
Cream	0.025%	0.05%	0.1%		
Gel		0.01%	0.025%	0.05%	0.1%
Solution					0.05%

preparations. The strength of a given preparation reflects its irritancy and probably also its efficacy. For tretinoin, the strength of the preparation depends both on the concentration of the drug and the nature of the vehicle in which it is contained (Table 209-1). Adapalene is marketed as a cream in a concentration of 0.1%, and as a gel in concentrations of 0.1% and 0.3%. Tazarotene is also available as a cream or as a gel, and each is available in concentrations of 0.05% and 0.1%, and as a foam in a concentration of 0.1%. Benzoyl peroxide gels are marketed in concentrations of 2.5%, 5%, and 10%. Salicylic acid is marketed in a large variety of preparations and concentrations. Sodium sulfacetamide is available as a lotion in 10% concentration. Patients are initially prescribed the mildest preparations, and the potency is increased at subsequent visits if necessary.

Skin irritation is the major side effect of the comedolytics and can be associated with overuse. Patients should be counseled to use no more than a pea-sized amount of medication for the entire face. Adjunctive use of emollients can also mitigate this effect. In addition, approximately 1% of patients develop a true allergic contact dermatitis to benzoyl peroxide, in which case permanent discontinuation of this agent is required. Given that topical retinoids may make the skin more susceptible to the effects of sunlight, patients should be instructed to avoid excessive exposure to the sun and to use oil-free sunscreens if they need to be exposed to the sun for prolonged periods. Additionally, patients should be told that benzoyl peroxide can bleach clothing and linens.

### Antibiotics

Antibiotics are also indicated for patients who have inflammatory acne lesions. Topical agents such as clindamycin and erythromycin preparations (Cleocin, Clindagel, Evoclin, T-Stat) can be used, although their use as monotherapy for more than a few weeks is not recommended because of slow onset of action and predictable emergence of antibiotic-resistant bacterial organisms. Combinations of benzoyl peroxide and erythromycin or clindamycin, or tretinoin and clindamycin, are often prescribed before oral antibiotics. Benzamycin gel (5% benzoyl peroxide and 3% erythromycin), and Benzacilin or Duac gels (5% benzoyl peroxide and 1% clindamycin phosphate) can be applied twice daily. Acanya gel (2.5% benzoyl peroxide and 1.2% clindamycin) can be applied once daily. Veltin or Ziana gels (0.025% tretinoin and 1.2% clindamycin) can be applied nightly.

If acne lesions are inflammatory and either are extensive enough to make topical therapy impractical (ie, involving neck, shoulders, and upper trunk) or are

unresponsive to a topical regimen, then systemic antibiotics are warranted. The tetracycline class is preferred in patients older than 8 years of age. The second-generation tetracyclines doxycycline and minocycline are preferred because of their flexible dosing options (twice daily, or once daily if using extended-release formulations Doryx [doxycycline], Oracea [doxycycline], or Solodyn [minocycline]), increased lipophilicity and follicle penetration, and high efficacy against *P. acnes*. However, doxycycline is more likely to cause photosensitivity, and minocycline can be expensive. In addition, although rare, drug hypersensitivity syndrome, Stevens-Johnson syndrome, and a lupus-like syndrome may occur with administration of minocycline. Erythromycin may also be used as an alternative, but it has the highest rate of *P. acnes* resistance among oral antibiotics prescribed for acne, limiting its efficacy. Resistance to *P. acnes* may affect as many as 25% of patients receiving antibiotics; therefore, measures should be taken to counter this trend, such as limiting the use of oral antibiotics to shorter periods, combining topical comedolytics (especially topical retinoids) with topical antibiotics, and avoiding the use of oral antibiotics as maintenance therapy.

### Systemic Retinoids

Isotretinoin (Absorica, Amnesteem, Claravis, Myorisan, Sotret, Zenatane) was approved by the US Food and Drug Administration (FDA) in September 1982 for use in treating severe cystic acne. Its original formulation, Accutane, is no longer commercially available. Isotretinoin reduces follicular keratinization, sebum production, and intrafollicular bacterial counts. The result of these (and possibly other) effects is a dramatic improvement in acne. The therapeutic effect usually takes several months to appear and often persists long after the course of therapy is discontinued. Historically, 6-month courses have been used. However, in recent years, some physicians focus more on total dose given instead of duration, aiming for a 100- to 150-mg/kg total dose. Unfortunately, side effects are common. Almost all patients experience mucocutaneous reactions (cheilitis, conjunctivitis, and dry mucous membranes of the mouth and nose), and extracutaneous complications also occur. For example, systemic retinoids can elevate plasma lipid levels, cause asymptomatic vertebral hyperostoses, and, rarely, cause depression and pseudotumor cerebri.

An association between isotretinoin and inflammatory bowel disease (IBD; in particular, ulcerative colitis) may exist in a small subset of patients. However, any association may be confounded by many factors, such as the overlap between the highest age of IBD

occurrence and the age when severe acne occurs and isotretinoin is used, an extended history of antibiotic use in most patients receiving isotretinoin, and the possibility of a link between IBD and inflammatory acne itself.

Although evidence supporting an association between isotretinoin and mood disorders exists, it has been almost all anecdotal, plus 1 small open-label study whose data were confounded by a disparity in acne severity between the 2 treatment groups, with the more severe cases receiving isotretinoin, which could be related to the more severe depressive symptoms in the group. By contrast, larger well-designed epidemiologic studies have not supported a cause-and-effect relationship between isotretinoin and depression. Rather, acne severity is a proven predictor of mental health issues and suicidal ideation. Although patients taking isotretinoin should still be carefully observed for mood changes, the evidence is reassuring.

Most important is the medication's teratogenicity. Exposure to isotretinoin in pregnancy has been associated with a 25-fold increased risk for major fetal malformations. Thus, female patients must exercise strict birth control while taking this drug. To ensure compliance with these guidelines and to prevent pregnancies from occurring during treatment, the FDA requires that all patients being prescribed isotretinoin be enrolled in a national registry. Isotretinoin is recommended only for those who have severe cystic or scarring acne (or both) and for a minority of patients who have severe noncystic acne and have not responded to therapy with topical comedolytics and oral antibiotics.

### Hormonal Therapy

Hormonal therapy can be an excellent option for women with moderate to severe acne if oral contraception is desired, an alternative to repeated courses of isotretinoin is preferred, or certain endocrine disorders are present. If a patient has no endocrine disorders, it is best to wait until 1 year after the onset of menstruation to allow the development of as much bone mineral density as possible before initiating oral contraceptives. All combination contraceptives reduce free testosterone and have a positive effect on acne, with no single preparation being demonstrably superior. Contraceptives containing only progestins should be avoided if possible, given that some of them have intrinsic androgenic activity and may aggravate acne. Only the progestins norgestimate, desogestrel, and drospirenone have no or low risk for increasing testosterone receptor activity and can be used in combination formulations. The relationship between oral contraceptive use and thromboembolism is under review by the FDA. A history of tobacco use and a family history of thrombotic events should be obtained before oral contraceptives are prescribed.

Spironolactone is an aldosterone antagonist that reduces receptor binding by testosterone and dihydrotestosterone in sebaceous glands and, like oral contraceptives, reduces free testosterone. Its efficacy may be apparent clinically more quickly than when oral contraceptives are used, often in 2 to 3 months

instead of 3 to 4 months. Its dose range is from 25 to 200 mg daily. Blood pressure and serum potassium levels should be monitored because, at higher doses, it can lower blood pressure and raise potassium levels.

### Patient Compliance

Patient compliance is the single most important aspect of successful acne treatment. Without patient compliance, even the most effective medications are doomed to failure. To maximize compliance, the physician must take time at the initial visit to explain in detail the use of each medication, as well as the effects and side effects to be expected. To reinforce these instructions, giving the patient printed instructions is helpful, an example of which is shown in Box 209-1. Depending on the situation, medications can be taken once or twice daily. If this activity is linked to an established daily routine, such as brushing the teeth, then it too can become habitual. Given careful, specific instructions, most patients who have acne are exceptionally compliant and, given time, obtain good results for their efforts. The concept that the treatment will take time to be effective needs to be emphasized to all patients; otherwise, they may become prematurely, and inappropriately, discouraged. The acne instruction sheet can also be used to answer several other questions, often unasked, that patients or their parents frequently have. The most common of these issues pertain to diet, cleanliness, cosmetics, and picking at the lesions.

### Diet

Although diet has long been dismissed as a factor in the development of acne, recent studies are changing that view. Research suggests that diets with a high glycemic load may exacerbate acne. High glycemic loads can lead to diet-induced hyperinsulinemia, which increases production of androgens, insulin growth factor-1 (IGF-1), and IGF-binding protein-3 (IGFBP-3) and decreases retinoid receptor activity. All of these changes stimulate follicular plugging and sebum production, thereby aggravating acne. Although more studies need to be completed before carbohydrate restriction can be strongly recommended for patients with acne, it is reasonable to recommend a low-glucose-load diet as an adjunct to existing acne therapy.

Although the evidence supporting an association between dairy intake and acne has not been as strong as that involving glycemic loads, dairy products may also have an effect on acne through changes in endocrine pathways. Milk contains testosterone precursors and 5- $\alpha$ -reduced molecules that are all converted to dihydrotestosterone after ingestion, stimulating sebum production and follicular plugging. Interestingly, skim milk has been particularly suspect in this regard because these ingredients are more bioavailable in skim milk. In addition, skim milk is associated with higher IGF-1 levels and contains less estrogen, a hormone that reduces acne. An even greater culprit is the fermentation process in cheese production, which increases testosterone production from androgen precursors. Although more research is needed to prove this link more rigorously, it would be fitting to advise

**BOX 209-1 Acne Instruction Sheet****TOPICAL MEDICATIONS**

1. Action
  - a. Help open up clogged pores.
  - b. Benzoyl peroxide and sodium sulfacetamide also help kill bacteria in the pores.
2. Method of use (apply to *all* affected areas)
  - a. Apply retinoid at bedtime.
  - b. *Do not* use acne scrub cleaners.
  - c. Apply benzoyl peroxide, salicylic acid, or sodium sulfacetamide in the morning.
3. Possible problems
  - a. May make the condition look worse in first several weeks, before improvement is seen (known as *bringing acne to the surface*).
  - b. May cause irritation (eg, redness, dryness, tenderness). If too much irritation occurs, then use every other night until the skin becomes accustomed to it. If irritation is severe, then medication should be stopped and a return visit scheduled.

**TETRACYCLINE**

1. Action: Helps kill bacteria; particularly useful for deep and inflamed lesions.
2. Method of use: Needs to be taken on an *empty* stomach. Therefore, take it as soon as you get out of bed in the morning (wait ½ hour before eating breakfast) and at bedtime (at least 1 hour after eating any evening snack).
3. Potential side effects
  - a. Uncommon; most patients have no trouble.

- b. May upset stomach and cause nausea, diarrhea, or both.
- c. Occasionally causes a yeast vaginitis, particularly if you are taking birth control pills.
- d. Should not be taken if you are pregnant or trying to get pregnant.

**GENERAL**

1. Diet: For most patients, foods have no effect on acne. If you notice that a certain food aggravates the condition, then simply avoid that food. Otherwise, no restrictions are necessary.
2. Washing: Acne cannot be washed off. Wash your face with a mild cleanser 2 to 3 times per day, and bathe or shower daily.
3. When to expect results from medicines: *It takes time*, usually several months, to begin to see benefits. At a return visit in 2 to 3 months, some improvement should be present, but the acne will not likely be cleared. The medications and their doses will be altered at that time, depending on the response.
4. Conscientious and *regular* use of the medications is essential. They will not do any good if not used regularly.
5. Cosmetics: They may aggravate your acne. If you must use them, then do so sparingly, and use only those that are water based. You may also consider some of the newer foundations that contain salicylic acid.
6. No picking!

patients that dairy products may incrementally aggravate their acne. However, if patients decide to avoid dairy products or to significantly reduce their ingestion, they also need to be counseled regarding vitamin D and calcium supplementation. As supplementation guidelines change, both physician and patient will have to adjust accordingly (see Table 209-2).

Although early studies asserted that eating chocolate does not affect acne, a recent preliminary study evaluating adolescent boys eating 6 ounces of 100% cocoa found that it significantly increased the number of comedones as soon as 4 days later. The cause was not clear. A randomized trial is underway to confirm these findings. Whether or not other dietary components such as omega-3 fatty acids, antioxidants, zinc, and fiber play a significant role in acne pathogenesis remains to be seen.

**Cleanliness**

The question of cleanliness is pondered more by parents than it is by patients. To help maintain peace at home, the notion that acne is a function of poor hygiene should be dispelled. It is not. In general, cleaning agents for acne need not be recommended because most irritate the skin, unnecessarily compounding the

irritation caused by topical comedolytics. The use of a mild soap-free cleanser is often suggested.

**Cosmetics**

Because cosmetics have been implicated as possibly contributing to the acne process, it is preferable to avoid using them. If cosmetics are used, then they should be water-based and used sparingly. If the eruption is prominent and negatively affecting the patient's self-image, corrective camouflage is an option.

**Picking**

For many patients who have acne, much of the skin damage is self-inflicted. Although the temptation to squeeze a fresh pustule can be overwhelming, the practice must be discouraged. Picking, probing, and squeezing cause more tissue damage and sometimes produce scars. For some patients with acne, picking may become so obsessive that excoriations are the only lesions seen.

**COMPLICATIONS**

The major complications of acne are its psychosocial ramifications. In addition to the cosmetic liability of active lesions, permanent scars compound and

**Table 209-2** Dietary Reference Intakes for Calcium and Vitamin D

LIFE-STAGE GROUP (AGE AND GENDER)	CALCIUM		VITAMIN D	
	RDA (MG/DAY)	UPPER LIMIT (MG/DAY)	RDA (IU/DAY)	UPPER LIMIT (IU/DAY)
0–6 mo (M + F)	200	1,000	400	1,000
6–12 mo (M + F)	260	1,500	400	1,500
1–3 yr (M + F)	700	2,500	600	2,500
4–8 yr (M + F)	1,000	2,500	600	3,000
9–13 yr (M + F)	1,300	3,000	600	4,000
14–8 yr (M + F)	1,300	3,000	600	4,000

RDA = recommended dietary allowance; intake that covers needs of 97.5% of the healthy normal population.

Reflects Adequate Intake (AI) reference value rather than RDA. RDAs have not been established for infants because of insufficient data.

Calcium and vitamin D RDAs are the same for pregnant or lactating females in these age groups.

Reprinted with permission from 2011 *Dietary Reference Intakes for Calcium and Vitamin D*, by the National Academy of Sciences. Courtesy of the National Academies Press, Washington, DC.

perpetuate the problem in some patients, mainly those who have inflammatory lesions. Established scars are difficult to treat. Many patients have been disappointed with the results of dermabrasion. Patients who have been treated with isotretinoin should wait for at least 1 year before having dermabrasion. Bovine collagen injections have been used in some patients, producing short-term improvement, but repeated injections are often necessary, and the long-term results are not yet known. Laser resurfacing by experienced operators has produced some promising results. Acne scars are best treated when inflammatory lesions are quiescent. Given that scars are easier to prevent than to treat, the emphasis in acne is on early, aggressive medical therapy.

## PROGNOSIS

With proper treatment, the prognosis for acne is good, if not excellent. Patients should understand that most therapy controls the disease instead of curing it and that improvement does not occur overnight. However, improvement does occur, usually within 2 to 3 months of starting therapy, and this time is best for the first scheduled return visit. At this visit, the acne regimen can be adjusted as necessary. For example, the potency of the comedolytics can be increased (or reduced) and the dose of the antibiotic altered, depending on the initial response. Continued improvement is to be expected with continuation of therapy. For many patients, the dose of systemic antibiotics can be reduced gradually and eliminated after 6 to 12 months. However, most patients also require prolonged maintenance therapy (often over years) with topical agents and, in some cases, continued topical antibiotic therapy.

Historically, cystic acne has been the most difficult to treat, but isotretinoin has become a powerful tool for dealing with this disease. This drug has the potential to effect prolonged remissions, sometimes lasting for years after a single course of therapy. However, as

discussed previously, isotretinoin has serious side effects, and its use is usually reserved for patients who have severe cystic or scarring acne (or both) that does not respond to standard treatment.

## WHEN TO REFER

- Patient is unresponsive to oral antibiotics and topical comedolytics.
- Patient has cystic or scarring acne.
- Patient is a young girl with acne or a girl with acne and irregular menses.
- Patient has acne fulminans (abrupt onset of cystic acne, fever, arthralgia).

## Chapter 210

## ADJUSTMENT DISORDER IN CHILDREN AND ADOLESCENTS

George Alvarado, MD; Danielle Laraque, MD

## FOUNDATION

## Definition

An adjustment disorder (AD) is a maladaptive response to a stressor, resulting in clinically significant emotional or behavioral symptoms not meeting criteria for a more specific disorder. Clinical significance is determined by marked distress that is in excess of what would be expected from exposure to the stressor or impairment in social or occupational (academic) functioning. Several subtypes of AD are distinguished by the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (*DSM-5*), based on the nature of the disturbance: with depressed mood; with anxiety; with mixed anxiety and depressed mood; with disturbance of conduct; with mixed disturbance of emotions and conduct; and unspecified. While there is no minimum duration of symptoms necessary to qualify for the diagnosis, symptoms must occur within 3 months of the onset of the stressor. Additionally, symptoms cannot persist for more than 6 months after the termination of the stressor, with the exception of cases of chronic adjustment, where the stressor is persistent.

## Epidemiology

While it is widely accepted that AD is common in childhood and adolescence, epidemiologic data, along with other types of research on the diagnosis, are fairly sparse. Looking at a sample of children in the general population in Puerto Rico, Bird and colleagues found a prevalence of 4.2% to 7.6%, depending on the cutoff score used on the Children's Global Assessment of Functioning Scale (GAF). Higher rates have been reported in clinical samples, including various pediatric settings. In a study conducted at an urban pediatric emergency setting, 14% of pediatric psychiatry consultations were diagnosed with AD. Another study of a suburban emergency department reported 34.4% of adolescents to have an AD diagnosis, the most common subtype being with depressed mood. The highest rates of AD have been found in those medically hospitalized, comprising up to 12% of referrals to psychiatry. While similar studies have not been done in children, it is reasonable to postulate that similarly high levels exist. With regard to medical diagnosis, high prevalence rates of adjustment have also been reported in children with chronic medical disorders, such as diabetes mellitus, with estimates between 36% and 60%.

## Etiology and Risk Factors

Given the requisite identification of a stressor, the causes of AD are necessarily broad, ranging from problems at home (eg, divorce) to conflicts at school, to interactions with peers, to acute and chronic medical illness. There may be a single or multiple stressors,

## BOX 210-1 Common Stressors

- Bullying
- Relationship breakup
- New school
- Parental divorce
- Economic stress
- Move, displacement, homelessness
- Medical illness/hospitalization
- Death of a loved one
- Sexual identity ("coming out," or being "outed")
- *Foster care placement*
- *Parental illness (including mental illness)*
- *Parental incarceration*
- *Parental substance abuse*
- *Witnessing domestic or other violence*

Italicized items indicate toxic stressors.

and they may be continuous or recur periodically. A stressor may accompany a specific life event, such as starting school, moving away from home, or becoming a parent. The single common pathway for all of these events is that they overwhelm the youth's ability for healthy coping, resulting in emotional, behavioral, or functional disturbance. Several common stressors are listed in Box 210-1.

Despite this wide range of stressors, it is important to note that none is uniformly overwhelming, so as to always result in an AD (with the important exception of toxic stress, indicated above and discussed later in this chapter.) Many children and adolescents may encounter highly stressful events without experiencing marked difficulties with adjustment. This fact points to the presence of important individual and environmental factors that can play a crucial role in moderating the role of stress on the individual. Such stressors have been designated as "tolerable," in the sense that, while challenging and nonnormative, they can be overcome, particularly with the help of a caring and involved adult relationship.

The concept of adaptation has been extensively studied in medically ill children, pointing to several factors that can affect the response to the stress of illness. These include individual factors of temperament, cognitive development, and problem-solving skills, as well as "social ecological" factors of family environment, social support, and availability of resources. Along these same lines, the concept of resilience serves to describe individuals who can achieve good adjustment despite high levels of stress or adverse events. In a study of the relationships of adverse life events to resilience, Tiet and colleagues found that "resilient youth received more guidance and supervision by their parents and lived in higher functioning families." Additionally, high IQ seemed to positively affect resilience for youth experiencing high levels of adverse life events.

In contrast to tolerable stress, toxic stressors, given their nature and timing in development, have been

shown to be almost uniformly deleterious to healthy development. Examples would include physical abuse or neglect, sexual abuse, parental depression, parental substance abuse, domestic violence, and other situations in which the primary caregiver is either directly causing the distress or otherwise failing to adequately mediate its effects. In practice, new-onset, seemingly tolerable stressors can often be superimposed on pre-existing toxic stressors, necessitating careful assessment in differentiating AD from a more pervasive problem resulting from trauma. Thus, a child with a history of several toxic stressors, presenting with a maladaptive response to new problem, will likely require a greater degree of intervention compared to a child with an otherwise stable caregiver relationship and unremarkable psychosocial history.

## DIAGNOSIS

With this wide range of causes and resulting manifestations of distress, appropriate identification of adjustment can be challenging. Given the absence of more concrete, objective criteria, diagnosis necessarily entails some subjective assessment on the part of the physician in regards to what constitutes a stressful event and a maladaptive response. The pediatrician is often in a unique position to make this determination. Whereas the mental health professional often first comes into contact with the child in the midst of a crisis, the pediatrician often has worked with the child and family over a long period of time and has a working sense of his or her developmental level, coping skills, and strengths. This can serve as an invaluable point of reference in assessing the effects of stress and the resulting departure from the child's psychological and functional baseline. It is in this context that the diagnostic construct of AD seems to provide the greatest clinical utility.

### Signs, Symptoms, and Differential Diagnosis

The signs and symptoms of AD include distress and impairment in functioning manifested by decreased performance in school, work, or relationships. Children and adolescents, as compared with adults, are more likely to present with behavioral disturbance than with depressed mood. However, the symptom presentation is also dependent on the subtype. For example, for young children with a depressed mood this may be manifested by sadness, tearfulness, change in appetite and sleeping pattern, or loss of interest in play. For older children and teens there may be irritability, loss of energy, fatigue, feeling slowed down or burned out, excessive feelings of guilt, inability to concentrate, indecisiveness, and hopelessness. Thoughts of suicide, substance use, and somatic complaints are also common. In those with the anxiety subtype of AD, symptoms of nervousness, worry, jitteriness, or fear of separation may predominate. Disturbances in conduct and emotions may also occur. In developing the differential diagnosis, careful review is needed to determine if the child or teen meets criteria for another disorder inclusive of but not limited to major depressive disorder, dysthymia, a generalized anxiety disorder, acute stress/post-traumatic stress, somatization disorder, oppositional defiant disorder,

conduct disorder, or substance abuse. Importantly, unlike the stressor in AD, in post-traumatic stress disorder the stressor is extreme and involves actual or threatened death or serious injury accompanied by a specific constellation of symptoms. Trauma always needs to be considered in the differential diagnosis. Conversely, a child may be suffering from the effects of early toxic stress (described earlier), and such a history should alert the physician to the possibility of complex developmental trauma and its attendant psychological and behavioral sequelae. Thus, a pattern of frequent, recurrent "adjustment reactions" can point to the presence of a more pervasive psychiatric disorder.

Box 210-2 is illustrative of a typical presentation in the primary care setting. The alerts for the physician are noted, as are the assessment strategy and shared-treatment planning and monitoring necessary with the child/adolescent and parent.

## MANAGEMENT

### Treatment Approach

In planning treatment for a patient with AD, the goals are to reduce emotional and behavioral distress and to improve functioning. Wissow and colleagues have described the *common factors* approach for the treatment of mental health problems in the primary care setting. Drawing from the active core elements of various evidence-based treatments, the model takes a transdiagnostic approach to the application of effective practice elements rather than applying a specific protocol for a certain diagnosis. This has been shown to help improve outcomes across a range of diagnoses and could be particularly useful in AD, given the subsyndromal, potentially evolving (transient, temporary) nature of this diagnosis. Common factors can provide well defined and manageable tools that physicians can use to further the discussion on mental health and engage patients in addressing these problems. This can be accomplished through interventions both at the level of the individual and the level of the larger environment, depending on the particular circumstances of the case.

At the individual level, fostering resilience—identifying and bolstering coping skills, as well as problem solving around issues related to the stressor—can be a good place to start. Parents can be important partners in this process, particularly for younger patients, by encouraging healthy means of coping. To this end, educating both the child and parents about the effects of stress and the role of coping can serve an important role in promoting recovery and wellness. Identifying other supports, such as teachers, counselors, or coaches, can provide additional sources of support in coping with stressors. Scheduling a follow-up psychosocial visit to check in with the patient is important to signal that the physician deems that the teen's distress merits attention and can determine whether the symptoms are improving or if further intervention is needed. Developing a safety plan in case symptoms worsen or dangerousness (suicidal or homicidal ideation) arises should also be discussed with the patient and his or her family.

Another potentially important avenue of intervention lies in the environment itself, given the pivotal

**BOX 210-2 Adjustment Disorder Case**

AJ is a 17-year-old who comes to the office for a chief complaint of throat pain. He is a senior in high school known to his physician since birth. He hasn't attended school in several days. His affect is depressed and he is anxiously moving about in the office.

The physician asks how he is. AJ says he doesn't feel well. His responses are short and uncharacteristic. After examining him and obtaining a throat culture, the physician sits down with AJ. In a relaxed manner she inquires a bit further and offers AJ the opportunity to talk a bit more. The physician learns that AJ is distraught because his girlfriend of 6 months broke up with him 1 week ago. He is not sleeping well, has lost his appetite, and has disengaged from a number of activities that he enjoys. He denies any drug or alcohol use. He is having trouble focusing in school. Review of system is otherwise normal. The physician is considering an adjustment disorder.

*What would be reasonable next steps in the evaluation?*

Reasonable next steps in the assessment include reviewing the symptoms' duration; determining if this is an AD; assessing the related risks to this patient, regardless of diagnosis; and determining the frequency and type of monitoring needed for AJ. The physician in this case has a longitudinal relationship with the teen and may have discussed issues of confidentiality, but a review of confidentiality and of the limits of confidentiality is appropriate at this session. AJ's reactions are in response to an identified stressor that is within the time period delineated by the definition of AD. In addition, while AJ has some symptoms of depression and anxiety, he does not meet criteria for major depression, depression not otherwise specified, or anxiety, as manifested by the relatively short duration of his symptoms.

A review of AJ's past psychiatric history as well as family psychiatric history is relevant since they will help target a youth at particular risk for bad outcomes. Assessment of functioning in his home, school, and personal life is relevant. Given this teen's depressed affect, a more formal assessment of depressive symptoms and also suicidal risk are relevant. It may also be important to identify additional stressors. Given his age, it is likely that applications for college are imminent and may be adding to this teen's distress at this point in time. Assessing school performance in general, family and school pressures are also relevant.

*Are there any screening tools that might be useful in this encounter?*

There are several tools that may be useful to the evaluation of youth in the primary care setting. Most of these tools are in the public domain, short, psychometrically sound, and helpful in the evaluation. The following tools are representative.

*Tools for Pediatricians* (see also the Tools for Practice section at the end of the chapter)

1. Pediatric Symptom Checklist (PSC-17): a general psychosocial screen for the identification of symptoms in the domains of attention, internalizing, and externalizing.

2. PHQ-9M: a modified screen for depression in teens; maps onto the DSM criteria for depression and has been modified to include questions on suicidality.
3. CRAFFT (car, relax, alone, forget, friends, trouble): queries teens regarding riding in a car with someone who is "high" with alcohol or drugs; whether the teen uses alcohol or drugs to relax; uses these alone; has forgotten events after using; whether family and friends are worried about his/her use; and whether he or she has gotten in trouble as a result of use. This validated tool is short, and scoring can be used to assess probability of abuse or dependence. The physician should also remember to inquire about tobacco use.
4. Risk assessment for suicide: The SAD PERSONS + Family History mnemonic is useful in this regard and includes **S**ex (females attempt more often but males are more likely to complete), **A**ge over 16, **D**epression (and comorbid conduct/impulsive aggression/anxiety), **P**revious attempts, **E**thanol abuse (or other substance), **R**ational thinking lost (eg, psychotic/intoxicated), **S**ocial supports lacking, **O**rganized plan present (highly lethal and unusual method with wish to die/concealment), **N**o significant other available (eg, a close friend); **S**ickness (stressors); and a first-degree relative who has completed a suicide.

*What are reasonable next steps before AJ leaves the physician's office?*

1. Review with AJ the results he reported on the PSC-17, CRAFFT, and PHQ-9M. These tools can facilitate a discussion. For example, ask for clarification regarding answers that are positive for a particular symptom. A sample question/comment may be "I see that you checked this off. Tell me more about that."
2. Establish the family/peer support available to the teen and discuss issues of confidentiality and the limits of confidentiality in the case of safety concerns about self-harm, harm to others, or harm from others.
3. Discuss suicidal risk using the SAD PERSONS mnemonic, with a clear plan for follow-up. For teens with increased risk, a discussion with the relevant family support person is indicated, including assessing for access to weapons or other lethal means. Psychiatric assessment may be needed along with possible hospitalization if there is imminent risk. Education regarding adjustment issues may help to alleviate some stress and may also help engage the child/teen in active treatment planning.
4. Assist the teen in identifying coping skills (eg, relaxation, deep breathing, talking to others, self-talk).
5. Actively engage the teen in discussion regarding returning to normal activities, including school attendance and participation in sports and other extracurricular activities. General sleep hygiene and encouragement of regular meals should be discussed.
6. Develop a treatment plan inclusive of the steps listed above.

role of stressors in adjustment problems. This can include parents, family, school, peers, or the larger community, all of whom can play a role in predisposing, precipitating, or perpetuating the presenting problem. For example, if bullying is leading to problems of maladjustment, contacting the school and discussing intervention strategies with the staff can be instrumental in improving the situation and alleviating individual symptoms. Many other forms of stressors (eg, a contentious parental divorce) do not lend themselves to similar types of swift intervention but require attention nonetheless, because they are likely to perpetuate or even exacerbate symptoms of adjustment over time. In this regard, lapses or failures in the relationship to the primary caregiver(s) can be particularly deleterious and difficult to correct. In this manner, treatment of AD calls for a broad, systemic view of the patient's problems. It also necessarily entails communication and collaboration with other systems of care outside of the traditional office setting.

### Specific Treatments, Indication for Admission, and When to Refer

Should problems with coping persist or worsen, referral to mental health services may be warranted. The treatment of choice is psychotherapy. While no empirically validated treatments exist specifically for the treatment of AD, there are many different forms of psychotherapeutic treatments for full-blown syndromes such as depression, generalized anxiety, disruptive behavior disorders, and trauma. These can, in theory, be applied to the prominent symptoms of the particular adjustment syndrome. Examples include cognitive behavioral therapy (CBT) and interpersonal therapy for depression, CBT for anxiety, and trauma-focused CBT. These treatments are delivered in a variety of individual and group formats; however, at present, little is known about the optimal structure, frequency, and intensity of these treatments in cases of AD. Looking again to the systemic aspects of adjustment, family therapy can be another important intervention to consider in cases of severe and persistent distress.

Similarly, medication does not have an established evidence base in the treatment of AD, and the US Food and Drug Administration has not approved any medication for the treatment of AD. Benzodiazepines have not shown efficacy in controlled trials in childhood anxiety, although they have been used clinically with SSRIs as adjunctive short-term treatment to address severe anxiety symptoms and facilitate exposure to CBT. Their role in AD has not been studied. They are contraindicated with substance use and have a side effect profile that includes sedation, disinhibition, cognitive impairment, and difficulty with discontinuation. In adults, in cases of prolonged stress, such as chronic illness and medical hospitalization, SSRIs have been used to help bolster resilience and recovery. There are no reports or similar studies in children with AD. Given the prominent psychosocial determinants of AD, the nonpharmacologic interventions outlined above are the treatments of choice.

Hospitalization of a child or teen with AD is unlikely to be necessary in the absence of severe impairment and active suicidal thoughts or plan. Ongoing follow-up with primary care or mental health specialty care is indicated for monitoring of symptom resolution and return to normal social functioning. Literature reviews indicate that more children and teens, as compared to adults, experience a poor outcome with continued disturbance and progression to specific disorders, although for most of them the prognosis is good. The area of prevention is not at all addressed in the literature and many important questions remain unanswered. Further research is needed to determine if AD is a subthreshold presentation of post-traumatic stress disorder; a variant of a less severe affective, anxiety or behavioral disorder; or an entirely different disorder independent of any of these conditions.

## Chapter 211 ADRENAL DYSFUNCTION

Phyllis W. Speiser, MD

Adrenal cortical disease, especially adrenal insufficiency, is far more common than adrenal medullary disease and often goes unrecognized for extended periods. Physicians caring for children should consider the diagnosis of adrenal insufficiency in any patient with unexplained hypoglycemia, growth failure, weight loss, vomiting, or lethargy. These nonspecific signs and symptoms may be mistaken for, and should be differentiated from, infection, malnutrition, gastrointestinal disease, inborn errors of metabolism, anorexia, chronic fatigue syndrome, and depression.

## ANATOMY AND PHYSIOLOGY

The adrenal glands each weigh approximately 4 g in term neonates at birth, which is equivalent to the weight of adult glands; however, adrenal size decreases by approximately 50% to 60% within the first week of life. The adrenal glands are made up of an inner medulla and an outer cortex that are linked by vascular supply and hormonal influence. Within the mature adrenal cortex are 3 functionally distinct zones: the glomerulosa, comprising approximately 15% of the gland; fasciculata, the largest zone, comprising approximately 75% of the gland; and the reticularis, comprising approximately 10% of the gland.

The adrenal medulla is regulated by the sympathetic nervous system and secretes catecholamines, whereas the 3 zones of the cortex secrete steroid hormones

categorized, respectively, as mineralocorticoids, glucocorticoids, and sex steroids. Mineralocorticoid production, exemplified by aldosterone, is principally regulated by the renin-angiotensin axis and by ambient potassium levels. Mineralocorticoids affect sodium and potassium homeostasis, and deficiencies in their production or action cause hyponatremia, hyperkalemia, and dehydration. Glucocorticoid and adrenal sex steroid production are primarily regulated by pituitary corticotropin (adrenocorticotrophic hormone [ACTH]) and hypothalamic corticotropin-releasing hormone, secreted mainly in the early morning hours (4:00 to 8:00 am). Cortisol is the main glucocorticoid, and dehydroepiandrosterone (DHEA) is the main adrenal sex hormone. The latter is only a weak androgen, but it may be converted via androstenedione to either estrogens or androgens. The placenta uses fetal adrenal DHEA to produce estrogens. The main gestational hormone so derived, estriol, excreted in maternal urine, is a sign of fetal viability. Rising levels of DHEA and its sulfate later in childhood signal adrenarche, which usually precedes the development of body hair and apocrine odor at puberty.

Glucocorticoids are generally catabolic, promoting protein and lipid breakdown and inhibiting protein synthesis. The effects of cortisol counterregulate those of insulin, increasing the concentration of glucose by stimulating gluconeogenesis and by decreasing glucose utilization in muscle. Amino acids and glycerol produced by catabolic actions of cortisol on protein and fat are used as gluconeogenic substrates. The net effect is increased production and conservation of glucose for use by essential tissues, such as the brain and red blood cells, at the expense of less essential tissues during times of stress or starvation. Supraphysiologic doses of exogenous glucocorticoids suppress growth by antagonizing the production and action of growth hormones (GHs).

Cortisol contributes to the maintenance of normal blood pressure through several mechanisms. Under normal baseline conditions, cortisol increases urine flow by stimulating glomerular filtration rate and decreasing water resorption. At high concentrations, cortisol acts as a mineralocorticoid agonist, causing sodium and water retention. Other vascular actions of cortisol include stimulating angiotensinogen synthesis by the liver and increasing vascular sensitivity to pressors. In the adrenal medulla, cortisol is required for the enzymatic activity of phenylethanolamine *N*-methyltransferase, which converts norepinephrine to epinephrine. Epinephrine stimulates cardiac output, as well as hepatic glucose production. Cortisol decreases capillary permeability as well as the production and activity of nitrous oxide and the vasodilatory kinin and prostaglandin systems during stress, preventing life-threatening hypotension. Cortisol or aldosterone deficiency, or both, often results in shock if unrecognized and untreated.

## ADRENAL INSUFFICIENCY

### History and Physical Examination

The symptoms of cortisol deficiency include lethargy, fatigue, weakness, dizziness, and anorexia. Signs

detected at physical examination include hyperpigmentation, orthostatic hypotension, tachycardia, and weight loss. These findings are nonspecific and gradual in onset, and they may be mistaken for infection, malnutrition, gastrointestinal disease, inborn errors of metabolism, anorexia, chronic fatigue syndrome, and depression. In some patients, gastrointestinal symptoms such as abdominal cramps, nausea, vomiting, and diarrhea are prominent. In adolescents and adults, sexual or reproductive dysfunction, or both, with decreased libido, potency, or amenorrhea may accompany either primary or secondary adrenal insufficiency. Orthostatic hypotension is more marked in primary than secondary adrenal insufficiency because primary adrenal insufficiency is often associated with both aldosterone and catecholamine deficiency.

The most commonly recognized screening laboratory findings are hypoglycemia and low plasma cortisol. Children with these findings should be referred to a pediatric endocrinologist for further evaluation. Children with chronic primary adrenal insufficiency often have hyperpigmentation of the skin and mucosal surfaces, which is the result of the high plasma corticotropin and accompanying melanocyte-stimulating hormone secretion that result from absent cortisol feedback. This hyperpigmentation may be difficult to appreciate in dark-skinned individuals. Clues to its presence may be hyperpigmentation of the creases of the palms and of the oral mucosal surfaces. In contrast, patients with secondary adrenal insufficiency tend to be pale. Another symptom of primary adrenal insufficiency is a craving for salt, which is a result of aldosterone deficiency and resultant sodium wasting. Weight loss and failure to thrive may also be observed. Loss of axillary or pubic hair is common among hypoadrenal patients, which is attributable to low levels of adrenal androgens.

Children with secondary adrenal insufficiency might have delayed growth and puberty and manifestations of GH and gonadotropin deficiencies, in addition to ACTH deficiency. Headaches, visual disturbances, polyuria, and polydipsia, or any combination of these reactions indicative of diabetes insipidus may also be seen in pituitary disorders. Physicians caring for children with chronic unexplained signs or symptoms such as those described previously should consult with a pediatric endocrinologist to determine whether a referral is required. Children in hypotensive crisis or shock at the time they seek care should be treated urgently in the office or transferred immediately by ambulance to the nearest emergency center.

### Pathologic Forms

Primary adrenal disease may be associated with either hypoplasia or hyperplasia related to variable adrenal function. The most common forms of adrenal disease involve either deficient or excessive cortisol production. Box 211-1 lists various causes of adrenal disease. Only the most commonly encountered disorders will be reviewed in detail in this chapter. Online Mendelian Inheritance in Man (OMIM) should be consulted for a more detailed discussion of rarer diseases; OMIM catalog numbers for each adrenal disease are listed in Box 211-1.

### Primary Causes of Adrenal Failure

In primary adrenal insufficiency in children younger than 18 years, the most common cause is congenital adrenal hyperplasia (CAH; 72%). Thirteen percent have autoimmune adrenal insufficiency, and the remaining 15% include various rare syndromes such as adrenoleukodystrophy, Wolman disease, triple A syndrome (ACTH resistance, achalasia, alacrima), Zellweger syndrome, and unexplained adrenal insufficiency. In non-CAH primary adrenal insufficiency, causes include autoimmune adrenal insufficiency, X-linked adrenoleukodystrophy, adrenal hypoplasia congenita, and the IMAGe syndrome (intrauterine growth retardation, metaphyseal dysplasia, adrenal hypoplasia congenita, and genital anomalies) (see Box 211-1).

CAH is the most common inborn error in adrenal function. It is most often caused by deficiency of steroid 21-hydroxylase. In classic severe salt-wasting CAH, both cortisol and aldosterone production are impaired, and adrenal androgen production is excessive. As a result of the lack of the vital hormones cortisol and aldosterone, both boys and girls are susceptible to potentially lethal adrenal insufficiency if untreated; this susceptibility is also true of other forms of CAH that interrupt synthesis of these hormones (eg, 3- $\beta$  hydroxysteroid dehydrogenase deficiency, cholesterol desmolase deficiency). Excess androgen production, a side effect of 21-hydroxylase deficiency, causes genital ambiguity in newborn girls. In contrast, however, boys affected with severe 21-hydroxylase deficiency have no overt genital anomalies, and may not come to medical attention until they seek care while in extremis. To prevent mortality from adrenal crisis, among other reasons, the United States and many other countries perform newborn screening for this disease. Prompt treatment with glucocorticoids and mineralocorticoids is life saving. About one-fourth of patients with classic CAH produce enough aldosterone to avoid salt-wasting crises and are termed *simple virilizers*.

A milder, nonclassic form of CAH not associated with genital ambiguity or adrenal insufficiency may be missed by newborn screening programs. Although nonclassic CAH is not always detected by random blood hormone measurements, it is much more prevalent at all ages than the classic forms of the disease. Because nonclassic CAH is characterized by less marked adrenal androgen excess, symptoms and signs typically do not develop before middle childhood. These symptoms and signs often include early pubic hair and rapid advances in height in both sexes. In many cases, these disorders either go undetected or are diagnosed in adolescent girls or women with hirsutism, oligomenorrhea, or acne. The mild form of CAH may be mistaken in girls for polycystic ovarian syndrome.

Not all persons with increased 17-hydroxyprogesterone typical of nonclassic 21-hydroxylase deficiency are symptomatic. Boys, in particular, are much less likely to be troubled by this mild adrenal hormone imbalance. Even some girls and women remain asymptomatic. Thus, children who do not exhibit precocious pubarche and adolescents who are not troubled with symptoms of androgen excess may not

require treatment, or they may discontinue treatment when symptoms have abated and growth is complete.

### Laboratory Evaluation

The diagnosis of CAH rests on both the clinical manifestations and the specific hormone measurements. Deficiency of steroid 21-hydroxylase can be identified by measuring high levels of hormones that serve as enzyme substrates. The gold standard test is a corticotropin-stimulated serum 17-hydroxyprogesterone, although analysis of serum or saliva levels of this hormone taken at 8:00 am may also be diagnostic. This circumstance is true because of the natural circadian pattern of endogenous ACTH secretion, which is highest between 4:00 am and 8:00 am. Measuring adrenal hormones in an endocrine specialty laboratory that employs strict quality-control standards is important to avoid false-positive high levels generated by nonspecific measurement of cross-reacting hormones.

Stimulated serum 17-hydroxyprogesterone levels are usually moderately increased, usually exceeding 1,500 ng/dL (approximately 45 nmol/L) in individuals affected with nonclassic 21-hydroxylase deficiency. In contrast, both basal and stimulated 17-hydroxyprogesterone levels are markedly increased, generally exceeding 10,000 ng/dL (approximately 300 nmol/L) in classic simple virilizing or salt-wasting CAH. Moreover, cortisol levels are invariably low and fail to respond robustly to stress or exogenous stimulation in classic forms of CAH. Early-morning basal serum 17-hydroxyprogesterone measurements below 200 ng/dL (approximately 6 nmol/L) usually rule out even mild forms of 21-hydroxylase deficiency. Newborn screening test results from filter paper samples are measured differently and are not comparable to serum hormone levels. Each state's laboratory has its own reference range for screening tests.

### Genetics

Phenotypic variability in CAH is attributable to allelic variation in the gene encoding active steroid 21-hydroxylase CYP21A2. The disease is inherited as an autosomal-recessive trait. More than 100 known disease-causing mutations have been found, but approximately 10 mutations comprise 80% to 90% of alleles in most populations. The spectrum of disease ranges from severe to mild, depending on which CYP21A2 mutations a patient carries. Genotyping can

be useful in verifying an equivocal hormonal diagnosis; it is particularly valuable in prenatal diagnosis and genetic counseling.

### Management and Long-Term Follow-up

CAH is treatable with oral corticosteroid medications. In its classic form, CAH requires lifelong medical management. Patients with salt wasting require both glucocorticoids and mineralocorticoids; however, with older age and increasing dietary salt consumption, mineralocorticoids may be tapered and in some cases discontinued. Infants who consume very little dietary sodium, patients in tropical climates, and those who engage in intense exercise with excessive sweat sodium losses may require supplemental sodium chloride. Poorly controlled patients with simple virilizing CAH also benefit from mineralocorticoid therapy because it spares the use of high-dose glucocorticoids in some cases. Symptomatic nonclassic patients require low-dose glucocorticoid therapy only. Some physicians prefer to treat CAH with a higher dose of cortisol or a longer-acting glucocorticoid at night in an attempt to suppress the early-morning ACTH-mediated adrenal androgen production, but there are scant data to support this practice.

When growth is nearly complete, if satisfactory control of adrenal androgens is not achieved with such a regimen, more potent and long-acting glucocorticoids, such as prednisone or dexamethasone, may be used. Table 211-1 lists approximate relative glucocorticoid potencies.

Dosing should be titrated to maintain the levels of adrenal androgen precursors in the normal to mildly increased range. The physician should assay 17-hydroxyprogesterone, androstenedione, and testosterone; plasma renin activity is added to this profile in patients requiring mineralocorticoid replacement. Attempts to suppress 17-hydroxyprogesterone to the normal range usually require excessively high glucocorticoid doses and have the undesirable consequence of growth suppression and iatrogenic Cushing syndrome. Measurement of ACTH is not helpful; this hormone seldom is completely suppressible in patients who have been treated for CAH. An important point to recognize is that testosterone is not as useful a hormonal marker of adequate therapy in adolescent boys and men, although it is helpful in managing prepubertal children of both sexes, as well as adolescent girls and women.

**Table 211-1** Glucocorticoid Potencies

DRUG	POTENCY RELATIVE TO CORTISOL	EQUIVALENT CORTISOL DOSE	MINERALOCORTICOID ACTIVITY
Cortisol (hydrocortisone)	1	100	Present
Cortisone	0.8	125	Present
Prednisone	5	20	Absent
Prednisolone	5	20	Absent
Methylprednisolone	6	17	Absent
Dexamethasone	50	2	Absent

Other aspects of CAH treatment include ensuring that adolescent girls with severe forms of CAH undergo gynecologic examination in anticipation of sexual activity; vaginoplasty may be necessary, depending on whether or which genital surgical procedures may have been performed in the past. Psychological counseling should be provided to these young women by a professional who is experienced in treating this type of disorder.

Adolescent boys should undergo careful testicular palpation and sonography to rule out testicular adrenal rests that can compromise fertility. Strict control of adrenal hormone levels can shrink such benign tumors in many cases.

### Other Causes of Adrenal Failure

Primary adrenal insufficiency is estimated to affect approximately 100 per 1 million people. The syndrome, originally described by English physician Thomas Addison, included wasting, hyperpigmentation, and adrenal gland atrophy. In adults, more than 80% of cases are caused by autoimmune adrenal destruction, which is most prevalent in women aged 25 to 45 years but which is observed in both sexes at any age. The female-to-male ratio is approximately 3:1. Autoimmune adrenalitis may be isolated or found in association with other autoimmune syndromes. Autoimmune polyendocrine syndrome type 1 is associated with mucocutaneous candidiasis, Addison disease, and autoimmune hypoparathyroidism. Other systemic problems may include autoimmune pernicious anemia, hepatitis, thyroiditis, and diabetes. The age at onset and severity of each of these problems are variable. Autoimmune polyendocrine syndrome type 2, also termed *Schmidt syndrome*, is associated with Addison disease, autoimmune thyroiditis, and diabetes. Box 211-1 lists the diseases associated with adrenal insufficiency.

Adrenal infiltration by tuberculosis is the second most common cause worldwide. HIV is another potential infectious cause of adrenalitis; both of these infections tend to cause insidious progression to hypoadrenalism. In contrast, catastrophic adrenal hemorrhage during overwhelming bacterial sepsis causes the abrupt onset of adrenal failure.

Perhaps because of its rarity in children or its non-specific symptoms, the diagnosis of adrenal insufficiency is often delayed or missed. If unrecognized, adrenal insufficiency may produce a life-threatening crisis, with acute cardiovascular collapse. The child's caregivers may have to seek the advice of more than one physician before a diagnosis will be made, which may result in a lengthy delay between the onset of the first symptoms and the diagnosis.

### History and Physical Examination

As noted previously, signs and symptoms of adrenal insufficiency may include abdominal pain, headache, anorexia, weight loss, lethargy, postural hypotension or shock, proneness to dehydration, salt craving, and hyperpigmentation. Patients with adrenal insufficiency with and without GH deficiency may have hypoglycemia, but this condition is seldom severe enough to cause seizures.

### Laboratory Evaluation

Primary adrenal insufficiency can be detected based on low early-morning (8:00 am) cortisol accompanied by increased ACTH. If zona glomerulosa function is affected, then hyponatremia and hyperkalemia will be accompanied by a high plasma renin activity and low serum aldosterone. In adrenal insufficiency resulting from pituitary or hypothalamic dysfunction, ACTH levels will be low. The diagnosis of primary adrenal insufficiency can be confirmed by absence of at least a twofold increment in serum cortisol 60 minutes after stimulation with a standard dose of intravenous cosyntropin (ACTH 1-24). A low dose of cosyntropin can be used to test ACTH reserve in cases of suspected secondary adrenal insufficiency.

### Imaging Studies

If adrenal hemorrhage is suspected, then it can be detected by ultrasonography or computed tomography (CT) scan.

### Management

When the diagnosis of adrenal insufficiency is established, frequent reminders to patients, families, and medical personnel regarding the need for higher doses of glucocorticoid replacement therapy during intercurrent illness and surgery are required. Failure to increase glucocorticoid supplementation during physical stress remains a significant cause of morbidity and mortality in these patients. Patients should be given letters explaining their condition and appropriate emergency management. Sample letters may be found on the Web sites of the National Adrenal Diseases Foundation for patients with Addison disease, and the CARES Foundation (Congenital Adrenal Hyperplasia Research Education and Support) for patients with CAH (see Tools for Practice).

### Secondary Adrenal Insufficiency

Secondary adrenal insufficiency is more common than primary adrenal insufficiency. The estimated prevalence is 150 to 280 per million people. Abrupt discontinuation of glucocorticoid therapy exacerbated by stress is the most common cause and results from the widespread use of exogenous glucocorticoids. Acute hypoglycemia has been reported after the use of inhaled glucocorticoids. An important point to recognize is that normal statural growth does not preclude adrenal suppression while being treated with inhaled glucocorticoids.

Administration of steroids orally, intramuscularly, intranasally, inhaled, transdermally, or intraorbitally may result in suppression of the hypothalamic-pituitary-adrenal axis. In adults, as little as 2 weeks of high-dose glucocorticoid treatment may result in suppression of endogenous cortisol production for up to 1 year. In children being treated for leukemia, a 4-week course of glucocorticoids may suppress the hypothalamic-pituitary axis for up to 8 weeks after discontinuation. Suppression of the axis cannot be reliably predicted by either the dose or the duration of therapy.

Documentation of an intact hypothalamic-pituitary-adrenal axis should be obtained before subjecting to

surgery a patient who has a known history of high-dose, long-term glucocorticoid treatment. This task may be accomplished by documenting plasma cortisol level taken at 8:00 am of more than 10 mcg/dL or by performing a cosyntropin (ACTH 1-24) challenge test and observing cortisol levels above 15 to 18 mcg/dL after 30 to 60 minutes. These levels have been derived mainly from adult studies and may not be relevant to infants and small children. Another robust test of ACTH reserve is insulin-induced hypoglycemia; however, many physicians are reluctant to use this test because of the danger of potential hypoglycemic seizures. If such documentation cannot be obtained in time, then treating patients with supplemental stress corticosteroid coverage in the perioperative period within 1 year of withdrawal of therapy is safest.

Most secondary adrenal insufficiency that is unrelated to withdrawal of glucocorticoid therapy occurs in association with other pituitary hormone deficiencies. *Panhypopituitarism*, or deficiency of 2 or more pituitary hormones, may be either congenital or acquired. Anatomic abnormalities in the pituitary or stalk may be evident on MRI. Alternatively, the physician may elicit a history of head trauma or cranial surgery with resulting pituitary injury.

Aside from these causes of secondary adrenal insufficiency, several other rare syndromes have been found. These syndromes include ACTH resistance associated with triple A syndrome (ACTH resistance, alacrima, and achalasia). This clinical picture is caused by mutations in the *AAAS* gene encoding a protein of uncertain function. In contrast, an isolated form of ACTH resistance is caused by a different genetic defect in the gene encoding the ACTH receptor *MC2R*. The latter syndrome is characterized by a familial form of glucocorticoid deficiency associated with hyperpigmentation and hypoglycemia without accompanying systemic abnormalities. Granulomatous diseases such as sarcoidosis or histiocytosis can also cause pituitary failure. The risk for adrenal crisis in adults with primary adrenal insufficiency is slightly higher (3.8 admissions per 100 patient-years) compared with secondary adrenal insufficiency (2.5 per 100 patient-years). Information concerning mortality in secondary adrenal insufficiency mostly comes from recent reports regarding follow-up of individuals treated with pituitary GH. An up to fourfold increase in mortality compared with the general population in children treated with pituitary GH has been reported. This increase is presumably because patients with a pituitary hormone deficiency are likely to develop other hormone deficiencies. Deaths were attributed to hypoglycemia or secondary adrenal insufficiency. These preventable deaths were observed in individuals of all ages and were associated with a variety of causes of hypopituitarism; 74% were said to occur in individuals with known multiple pituitary hormone deficiencies. The death rate resulting from secondary adrenal insufficiency remained fairly constant throughout middle childhood and with advancing age (1 per 113 to 173 person-years).

Management of secondary adrenal deficiency is similar to that of primary adrenal insufficiency. Measuring ACTH or cortisol levels in plasma to gauge the

efficacy of treatment with corticosteroids is usually not helpful. Rather, the patient's growth, weight gain, and vital signs, as well as the patient's own sense of well-being, should guide therapy.

## RELATIVE ADRENAL INSUFFICIENCY IN THE INTENSIVE CARE UNIT

Annane and colleagues found that critically ill adults with a normal baseline cortisol but inappropriately low response of serum cortisol to acute stimulation demonstrated improved survival when treated with stress doses of hydrocortisone, although these findings have not been replicated.

Among critically ill children, a low incremental cortisol response to ACTH does not predict mortality, although the effect of glucocorticoid treatment is not known.

Much controversy still exists regarding how best to look for adrenal insufficiency in hospitalized children and adults, as well as whether and when to treat. Thus, the decision to treat a critically ill patient with glucocorticoids must be made on a case-by-case basis until further definitive evidence is available.

## MANAGEMENT OF ACUTE ADRENAL INSUFFICIENCY

Hypotension and lethargy are common signs at presentation of acute adrenal insufficiency; patients and family members should be taught to recognize a change in energy level or demeanor as a potential warning sign. Acute adrenal insufficiency may occur during febrile illness, especially when accompanied by dehydration, vomiting, diarrhea, or any combination of these reactions. Individuals who are unable to tolerate oral maintenance or stress doses during an illness require parenteral glucocorticoid administration. Another option, especially if parenteral administration is not feasible, and provided that the patient does not have diarrhea, is to administer hydrocortisone suppositories.

After the patient is seen in the emergency department, a large-bore intravenous catheter should be inserted for repletion of intravascular volume with saline solutions containing 5% dextrose. More concentrated dextrose (eg, 25% dextrose in water) should be administered to treat refractory hypoglycemia. If the patient's adrenal status is unknown, then blood should be drawn for cortisol, electrolytes, glucose, ACTH, plasma renin activity, and aldosterone, preferably before exogenous steroids are administered. If acute and severe adrenal insufficiency is suspected, however, then treatment should not be delayed for diagnostic testing. Simultaneous with the administration of fluids, stress doses of glucocorticoids should be given. Hydrocortisone is the treatment of choice because of its quick onset of action and mineralocorticoid activity. Prednisone and dexamethasone are long-acting glucocorticoids with a slower onset of biologic action. Table 211-1 lists the relative potencies of various steroid medications. Prednisone is not an ideal choice for treating acute adrenal crisis because it must be converted to prednisolone to be effective. Dexamethasone does not cross-react in cortisol

assays; thus, a diagnostic ACTH stimulation test may be performed right after its administration.

Liberal quantities of intravenous sodium chloride accompanied by large doses of hydrocortisone will usually restore normotension and correct electrolyte abnormalities, obviating mineralocorticoid treatment or pressor agents in the acute situation. As vital signs stabilize, glucocorticoids and fluid infusions are tapered over several days. When the patient is able to eat and take oral medications, oral glucocorticoids may be substituted. Supplemental sodium chloride may be provided if dietary salt intake is inadequate.

### Chronic Replacement Therapy

Maintenance glucocorticoid replacement therapy is based on estimated normal cortisol secretion rates. Glucocorticoid dosing must be individually adjusted to avoid signs and symptoms of adrenal insufficiency while also avoiding the growth retardation and cushingoid features that can accompany overtreatment. When growth is complete, longer-acting glucocorticoids such as dexamethasone may be considered to enhance compliance. In general, lower doses of glucocorticoids are required to treat Addison disease compared with CAH. Measuring plasma cortisol or ACTH levels in titrating the glucocorticoid dose is not usually helpful. Patients with low serum sodium, high potassium, or increased plasma renin activity should receive daily oral fludrocortisone and sodium chloride supplements, adjusted to normalize these analytes. The patient's own sense of well-being, energy level, and blood pressure can help guide the adequacy of therapy in patients with Addison disease. Frequent headaches, lethargy, nausea, or abdominal pain may indicate inadequate treatment. Objective signs of inadequate replacement therapy are orthostatic pulse or blood pressure changes. If skin hyperpigmentation becomes more prominent in primary adrenal insufficiency, then plasma ACTH levels may be helpful.

DHEA has been considered an optional hormone supplement for older women with adrenal insufficiency and low energy or libido, but no data on its use in adolescents have been collected.

### Stress Dosing

Patients with adrenal insufficiency (primary or secondary, and patients with CAH) must be informed about the need to increase their glucocorticoid dose during stress to prevent a potentially lethal adrenal crisis. All such patients should wear a medical alert tag and carry an emergency medical information card to ensure that medical providers know about the underlying disorder.

Mild physical stresses such as immunizations, uncomplicated viral illnesses, and low-grade fever (temperature  $<101.3^{\circ}\text{F}$  [ $<38.5^{\circ}\text{C}$ ]) do not require stress doses of glucocorticoids. Athletic activity and emotional stress also do not usually require a boost in glucocorticoid dose. Adolescents with CAH who received an additional morning dose of hydrocortisone causing a 100% increase in serum cortisol level did not alter their athletic performance. No changes were observed in blood glucose, lactate, free fatty

acids, or epinephrine levels during short-term, high-intensity exercise compared with placebo.

More severe stresses such as illness accompanied by higher fever (temperature  $\geq 101.3^{\circ}\text{F}$  [ $\geq 38.5^{\circ}\text{C}$ ]), surgery, and major trauma should be accompanied by tripling of oral hydrocortisone maintenance doses to prevent hypoglycemia, hypotension, and even cardiovascular collapse. Supplemental parenteral hydrocortisone is suggested before general anesthesia and surgery. Doses are empiric and are not determined by evidence-based guidelines. Intravenous or oral stress doses may be gradually tapered as the patient recovers until the maintenance dose is attained.

## ADRENOCORTICAL HYPERFUNCTION

The spectrum of disorders causing adrenal hyperfunction (Box 211-2) is more limited compared with those causing hypofunction.

### Premature Adrenarche

Adrenal androgen excess is most commonly observed in children with early onset of pubic and body hair growth. The traditional age limit has been 8 years for the onset of pubic hair in girls and 9 years in boys. The lowest age limit for girls has been contested after a large cross-sectional study revealed the relatively common occurrence of either early pubic hair or breast enlargement in healthy black girls after age 6 years and in white girls after age 7.

### Definition

The early onset of adrenal androgen secretion accompanied by pubic hair (*pubarche*) is termed *premature adrenarche*.

### BOX 211-2 Causes of Adrenal Cortical Hyperfunction

ACTH, adrenocorticotrophic hormone; AD, autosomal dominant; OMIM, Online Mendelian Inheritance in Man.

### Laboratory Evaluation

Premature adrenarche is heralded by mildly increased levels of DHEA and DHEA-sulfate. These hormone levels tend to be consistent with the child's Tanner stage of pubic hair. DHEA, a weak androgen, is the most abundantly produced adrenal steroid. The sulfated form has a longer half-life in the circulation and thus is not subject to circadian variability, making it a more robust screening tool. Premature adrenarche is generally considered a benign condition that does not warrant treatment with glucocorticoid suppression. Presence of isolated pubic hair or axillary hair with or without apocrine body odor does not necessarily presage early breast development and menstruation. In most cases, children with premature adrenarche do not exhibit rapid statural growth or advanced bone age.

Because premature adrenarche is most often a benign condition, telephone consultation with a pediatric endocrinologist should be considered before referring such children. Endocrine evaluation should be reserved for children who exhibit unusually early pubarche, multiple signs of early puberty, rapidly progressive pubertal development or statural growth (or both), or nonisosexual puberty (eg, a girl with hirsutism or other signs of virilization, a prepubertal boy with gynecomastia).

Overweight children secrete more adrenal sex hormones than lean children and can metabolize these weak adrenal sex hormones in fat to more active sex hormones. Mean free testosterone is sixfold higher in obese girls than nonobese girls across pubertal stages 1 to 3. Consequently, they may develop secondary sexual characteristics at an earlier than average age. In contrast to nonobese children with premature adrenarche, obese children often show advanced bone ages, but they are not usually short.

Most overweight and obese children who are growing in height at a normal pace do not have a causal underlying endocrine disease. Thus, the pediatrician should institute dietary counseling and advise a rigorous exercise program to determine whether weight gain can be controlled. Telephone consultation with a pediatric endocrinologist is advised if in doubt. Reports have surfaced that a subset of girls with premature adrenarche go on to develop polycystic ovarian syndrome, insulin resistance, or metabolic syndrome. The precise cause of this tendency is uncertain but has been related to prenatal growth restriction, especially with rapid postnatal catch-up growth. In light of the role of obesity in androgen excess, intuitively, individuals with body mass indices in the overweight to obese range might be at highest risk. At present, no strong evidence has been found to warrant preventive drug treatment in anticipation of the possible occurrence of polycystic ovarian syndrome in young girls who have had premature adrenarche.

The differential diagnosis of premature adrenarche includes nonclassic forms of CAH and adrenal virilizing tumors. The most common nonclassic form of CAH can be detected by measuring early-morning or ACTH-stimulated levels of 17OHP. The much rarer occurrence of tumors can be detected by finding markedly increased levels of DHEA-sulfate and often

other hormones as well. Imaging studies are required to verify a clinical suspicion of an adrenal tumor.

### Cushing Syndrome

*Cushing syndrome* refers to any form of glucocorticoid excess, whereas *Cushing disease* refers to glucocorticoid excess caused by ACTH hypersecretion. Although Cushing disease is rare, it is the most commonly identified noniatrogenic etiology for glucocorticoid excess in adolescents, occurring in approximately 0.5 per million persons per year. Box 211-2 lists causes of glucocorticoid excess.

### History and Physical Examination

Prominent clinical features of adrenocortical hyperfunction in adolescents are excess central body weight gain with stunted statural growth. An important point to emphasize is that most obese adolescents do not have Cushing syndrome and do not require screening unless growth arrest or other suspicious signs are observed. An obese child with statural growth arrest should be referred to a pediatric endocrinologist for more complete evaluation. Examination of annual school photographs can often help reveal subtle changes in physiognomy and habitus over time. Other characteristic findings are easy bruisability, broad and purplish striae, hyperglycemia, and hypertension.

Therapeutic glucocorticoids are in widespread use for a variety of inflammatory and neoplastic diseases. Exogenous administration of relatively high doses of these drugs over long periods by any route is the most common cause of Cushing syndrome as well as secondary adrenal insufficiency. Although the relative safety of alternate-day oral and inhaled glucocorticoids has been demonstrated, individual differences in drug metabolism or sensitivity may cause an increase in bioavailable levels of these potent compounds, many of which have very long biologic half-lives. Therefore, obtaining a thorough medication history in children treated with these drugs is important. If possible, glucocorticoids should be tapered as soon as is practical while substituting other therapeutic agents. In some patients, attenuation of cushingoid features and improvement of statural growth may take months to years.

### Laboratory Evaluation

Clinical suspicion of Cushing syndrome in the absence of exogenous glucocorticoid administration should prompt appropriate screening diagnostic studies, including measurement of increased midnight salivary cortisol, high 24-hour urinary free cortisol, or both. The diagnosis may be confirmed by finding a non-suppressed morning cortisol after dexamethasone administration. The latter test has been refined by the postdexamethasone administration of corticotropin-releasing hormone. An inappropriately brisk rise in plasma ACTH after corticotropin-releasing hormone suggests an ACTH-producing pituitary tumor, and MRI with attention to this portion of the brain is indicated. If the tumor cannot be localized by imaging, then selective catheterization of the inferior petrosal sinuses with measurement of ACTH level on either side may be done at a specialized center. Ancillary

laboratory studies often reveal impaired glucose tolerance and low bone density on radiographs or dual x-ray absorptiometry.

Adrenal carcinomas (but not typically adenomas) will secrete cortisol as well as mineralocorticoids and androgens. Adrenal tumors are the most common cause of endogenous steroid excess in young children. The typical case appears in a round-faced, ruddy child with rapidly advancing premature pubarche, hypertension, and an abdominal mass. If adrenal carcinoma is suspected based on ACTH-independent (ie, nonsuppressible) cortisol excess, then the patient should undergo additional hormone measurements of aldosterone and plasma renin activity as well as DHEA-sulfate and androgens.

### Imaging Studies

Thin-slice CT or MRI of the abdomen including the adrenal glands should be performed. Carcinoma will often show a necrotic center, calcification and irregular borders, or both, whereas benign nonfunctioning adenomas are typically more similar in density to normal adrenal tissue and are homogeneous. Ectopic ACTH production by carcinomas is almost never seen in children.

### Management

Cushing disease has traditionally been treated primarily with transsphenoidal tumor resection. Surgical success largely depends on the skill of the surgeon and the nature of the lesion. The cure rate ranges from 60% to 80%. Data show that directed radiotherapy, such as gamma knife and linear accelerator techniques, can also induce gradual remission of ACTH hypersecretion. After ACTH levels have decreased, the patient needs chronic glucocorticoid replacement therapy.

Patients with an adrenal tumor or nodular hyperplasia as the source for cortisol excess will most often undergo adrenalectomy. Another alternative for Cushing syndrome or Cushing disease is medical therapy with drugs such as ketoconazole or mifepristone. This therapy can be used either in the short term (eg, while waiting for radiotherapy to take effect) or the long term to reduce cortisol secretion; however, this type of treatment will not induce a permanent cure.

## Adrenal Medullary Diseases

### Neuroblastoma

In young children, the most common tumor encountered is a neuroblastoma. The yearly incidence is approximately 1 in 100,000 children younger than 15 years. The average age at diagnosis in North America is 2 years; mass screening of infants is done in Japan to allow earlier diagnosis.

Common presenting signs include abdominal mass, fever of unknown origin, hematuria, spinal cord compression, pathologic fracture, and hypertension. Metastases to liver and bone occur in approximately 50% of cases by the time of tumor detection. Biochemical markers include plasma and urinary dopamine, vanillylmandelic acid, and homovanillic acid.

Bone scan is usually informative, revealing bone metastases, soft tissue calcifications, or both. Other imaging modalities are discussed later in this chapter

in conjunction with pheochromocytoma diagnostic tests. The medical and surgical management of such tumors depends on staging risk; a possibility exists of spontaneous regression in low-grade tumors.

### Pheochromocytoma

**HISTORY AND PHYSICAL EXAMINATION.** In the adolescent, medullary disease is most often caused by a pheochromocytoma, a rare tumor that may cause either episodic or chronic hypertension, usually accompanied by tachycardia, headaches, anxiety, sweating, flushing, or any combination. Weight loss may also be observed. The differential diagnosis in adolescents most saliently includes panic attacks, thyrotoxicosis, renovascular disease, and drug abuse (especially cocaine or amphetamines).

**LABORATORY EVALUATION.** Screening tests, besides documenting hypertension in the office, may include 24-hour ambulatory blood pressures. Chemistry profile may demonstrate hyperglycemia. Such findings should prompt referral to appropriate specialists. Extreme hypertension in a child should prompt immediate emergency referral and hospitalization.

The diagnosis of pheochromocytoma is made by measuring increased 24-hour urinary free metanephrines (collected in an acid container). Urinary free metanephrines are superior to urinary vanillylmandelic acid, urinary catecholamines, and plasma catecholamines. Alternatively, high-performance liquid chromatography is used for measurement of plasma free metanephrines. Blood should be obtained from an indwelling venous catheter in a patient who has fasted overnight and has been at rest for at least 20 to 30 minutes; the sample tube must be iced and processed immediately. If possible, psychoactive drugs, especially tricyclic antidepressants, should be discontinued at least 2 weeks before testing.

**IMAGING STUDIES.** Confirmatory imaging may be done by metaiodobenzylguanidine scan. Metaiodobenzylguanidine is a norepinephrine analog labeled with radioiodine that is taken up specifically by catechol-producing tumor tissue but not normal adrenal medulla. This imaging test is particularly helpful in cases in which thin-slice, contrast-enhanced CT or MRI fails to show a mass, yet biochemical tests and the clinical scenario are suggestive of pheochromocytoma. Other new imaging options include positron emission tomography and use of somatostatin analogs.

A thorough family history should be obtained for endocrine tumors, especially medullary thyroid carcinoma and hyperparathyroidism, because multiple endocrine neoplasia type 2 may be associated with pheochromocytoma. Genotyping for the *RET* oncogene should be performed in the patient, and, if positive, other family members should be tested. Transmission is autosomal dominant. Other syndromes prone to adrenal tumors or pheochromocytomas include von Hippel-Lindau disease, neurofibromatosis type 1, paraganglioma, and tuberous sclerosis. Approximately 30% of young patients with pheochromocytoma have one of these familial disorders and should therefore be genotyped for the appropriate genes. Familial cases are more often bilateral.

Children with a family history of familial tumor syndromes should be referred to the appropriate specialists for evaluation because early detection of affected genetic status may dictate intervention before tumors develop.

**MANAGEMENT.** Calcium channel-blocking drugs such as nifedipine are primarily used to control hypertension because calcium is needed for catechol secretion. In preparation for surgery, the patient should be treated for at least 1 week with a drug with both alpha-adrenergic blocking (eg, phenoxybenzamine) and beta-adrenergic blocking (eg, labetalol) properties. Unopposed alpha blockade would precipitate a hypotensive crisis at surgery, whereas unopposed beta blockade would exacerbate the hypertension from endogenous epinephrine, a potent vasoconstrictor. In addition, alpha-methyl-L-tyrosine (Demser) is used to inhibit the rate-limiting step of catechol synthesis. Approximately 10% of pheochromocytomas are bilateral, and thus, at the time of surgery, both adrenals should be explored. If both adrenals are removed, then substitution therapy will be required as primary adrenal insufficiency. Malignancy and recurrence may occur in approximately 10% to 15% of cases. Careful long-term follow-up of patients with regular checks of blood pressure and catechol measurements are crucial.

## Chapter 212

# ALLERGIC RHINITIS

Frank S. Virant, MD

Recent data from the National Health and Nutrition Examination Survey (NHANES III) suggest that 45% of children 6 to 9 years of age and 55% of children 10 to 19 years of age have sensitization to at least 1 of 10 common allergens. The most common clinical manifestation of sensitization is allergic rhinitis. Although some children have only rhinitis, many experience associated asthma or atopic dermatitis. Allergic rhinitis is relatively uncommon before the age of 3 years, but then increases in frequency throughout childhood, with a peak prevalence in adolescence. Seasonal allergic rhinitis caused by pollens often becomes apparent in early school-aged years and is quite obvious in the spring, summer, or early fall. Perennial allergic rhinitis caused by dust mites, cockroaches, animal dander, or indoor mold can occur at any age, but typically is more subtle and can be easily confused with other forms of rhinitis.

## ETIOLOGY

The likelihood of developing allergic rhinitis has a significant genetic component: if one parent has allergic rhinitis, the likelihood for a given child is 40%; if both parents are affected with allergic rhinitis, the likelihood jumps to 80%. When a child with genetic predisposition to allergic rhinitis is exposed to a relevant allergen, specific immunoglobulin E (IgE) is produced, which then binds to high-affinity receptors on mast

cells in the upper airway. Further exposure to the allergen activates a type I (immediate hypersensitivity) reaction as IgE binds to the allergen, triggering the release of preformed mediators, such as histamine, and the production of others, such as prostaglandins, leukotrienes, and cytokines. Histamine causes most of the immediate clear rhinorrhea, congestion, and sneezing seen with allergic rhinitis. Cytokines primarily guide inflammatory cells, such as eosinophils, to the site of reaction, leading to more edema (congestion) and nasal hyperresponsiveness. Severity of symptoms is influenced by several factors, including condition of the nose before exposure, level of specific IgE, and intensity of antigen exposure.

Common allergic rhinitis allergens include the following:

- *Dust mites*: These arthropods represent the major allergen in house dust and prosper in warm, moist indoor environments. They survive off shed human skin cells, and therefore tend to be particularly an issue on pillows, mattresses, and carpets. Dust mites are the major cause of perennial allergic rhinitis.
- *Cockroaches*: Much like dust mites, cockroaches thrive in warm, humid areas and are a common urban reason for perennial allergic rhinitis.
- *Animals*: Dander and saliva from cats and dogs can cause more subtle perennial as well as severe intermittent symptoms. Rodent allergens (also found in urine) can occur from pets such as hamsters, gerbils, or guinea pigs as well as from unwanted pests such as mice and rats.
- *Molds*: Indoor molds can be an issue if moisture accumulates at high levels, such as in poorly ventilated bathrooms or at the base of single-pane windows. Outdoor molds can cause seasonal symptoms during the spring, summer, and fall in colder areas or year-round in warmer climates.
- *Pollens*: Trees (late winter, spring), grasses (spring, summer), and weeds (summer, fall) represent the major reason for seasonal allergic rhinitis symptoms. Clinical presentation varies greatly by location and can be affected by several factors, including ambient temperature, precipitation, wind, local vegetation, and size of pollen grains. In a particular region, however, the reappearance of major allergens is highly predictable each year.

## CLINICAL FEATURES

Typical clinical features of allergic rhinitis include clear rhinorrhea, sneezing, congestion, and localized pruritus (nose, eyes, and occasionally palate, pharynx). Younger children generally have perennial allergic symptoms caused by dust mites, cockroaches, animal dander, or indoor molds. Seasonal pollen allergy often becomes evident by 4 to 5 years of age, but can also start much later in childhood because of individual variations in genetic predisposition to make IgE, as well as geographical differences in pollen distribution. The diagnosis of seasonal allergic rhinitis is often based on the patient's history and knowledge of local pollen seasons. Specific pollen counts can add further support for the diagnosis (local pollen counts from certified stations are logged on the American

Academy of Asthma, Allergy and Immunology Web site [www.aaaai.org]). Although children with perennial allergic rhinitis may have episodic rhinorrhea and sneezing, the primary clinical effect is from inflammation and associated congestion of the upper airway. This can lead to a multifaceted clinical picture, including frequent viral upper respiratory infections (URIs), chronic serous otitis media, recurrent suppurative otitis media, nasal speech, decreased hearing, mouth breathing, snoring, poor sleep pattern, and fatigue. Perennial allergic rhinitis also increases the risk for bronchial hyperresponsiveness during viral URIs. Rhinorrhea caused by allergic triggers is typically clear and watery, but this can be overshadowed by purulent secretions if the child also has infectious rhinitis or sinusitis. Histamine release often creates intense itching in the nose and oropharynx, leading patients to intensely rub their nose (the "allergic salute") or make strange clucking or throat-clearing noises to try to get relief.

The physical examination in moderate to severe uncomplicated allergic rhinitis shows pale, bluish, boggy turbinates with a clear serous discharge. Often, the turbinates are so enlarged that they touch the nasal septum and can completely occlude the upper airway. Because of chronic congestion and associated obstruction of venous drainage, many children have dark, swollen infraorbital areas, or "allergic shiners." Other common findings are Dennie-Morgan lines (extra folds under the lower eyelids caused by edema and rubbing) and an allergic crease (horizontal line across the lower bridge of the nose caused by rubbing). Children with more severe chronic allergic rhinitis are obligate mouth breathers; this can lead to elongated facial growth and various orthodontic changes (eg, overbite and high-arched palate). Tonsils and adenoids are often enlarged because of allergic immune stimulation (but this can also be a separate primary problem). Chronic middle ear effusion is also common in children with more severe allergic rhinitis. Although nasal polyps may occur with intense allergic disease, this is rare in childhood and more commonly caused by cystic fibrosis or eosinophilic nonallergic rhinosinusitis.

## COMPLICATIONS

In younger children, significant perennial allergic rhinitis causes increased swelling in the upper airway (nose, eustachian tubes, sinus ostia), creating an environment that may increase the incidence of respiratory infection, acute otitis media, chronic serous otitis media, eustachian tube dysfunction, hearing loss, and sinusitis. Chronic congestion from allergic rhinitis can also lead to elongated facies, high-arched palate, and malocclusion of the teeth caused by tongue thrusting. Upper airway allergic disease can increase bronchial hyperresponsiveness and thus lower the threshold for asthma as a result of other triggers, such as viral URIs, cold air, dry air, and exercise.

## LABORATORY FINDINGS

Nasal cytology can be a useful diagnostic adjunct when the clinical diagnosis of allergic rhinitis is in question. Secretions from the nose can be obtained by

having the child blow the nose onto plastic wrap or by swabbing the nose with a cytology brush. The secretions are then transferred to a glass slide, dried, and treated with either Hansel stain or Wright stain. If cellular microscopy reveals more than 10% eosinophils, then underlying eosinophilic rhinitis is suggested. In most children, this cellular response is caused by allergy, but eosinophilic nonallergic rhinitis cannot be excluded; this can be clarified by the presence or absence of specific IgE to allergens, as discussed later. Concurrent infection will create a significant neutrophilic response that can obscure underlying allergy, and the absence of eosinophils in a nasal smear does not preclude allergy because the sample of secretions may not be adequate (few cells) or may be influenced by recent corticosteroid therapy.

Peripheral eosinophilia is often observed in patients who have allergic rhinitis with more than 5% eosinophils or a total eosinophil count of more than 250/ $\mu$ L. Elevated total IgE does suggest atopy, but many patients with allergic rhinitis have levels in the normal range, and some patients with normal levels are atopic. Accordingly, peripheral eosinophil counts and total serum IgE are not recommended for allergic rhinitis screening because they are neither specific nor sensitive.

Determination of specific IgE with skin or serologic tests can be useful to help direct environmental control and determine appropriate components for immunotherapy. Overall, both types of tests tend to provide the same information, but skin tests are often preferred because they are less expensive and have somewhat better sensitivity. If a child has a poor clinical course despite aggressive environmental controls and appropriate frontline medications, referral to a board-certified allergist is recommended.

## DIFFERENTIAL DIAGNOSIS

The diagnosis of seasonal allergic rhinitis is generally straightforward based on clinical presentation, physical examination, and a knowledge of the local pollen pattern. In contrast, the diagnosis of perennial allergic rhinitis can be more challenging because symptoms are often more subtle or may be obscured by other conditions that cause rhinorrhea, congestion, and cough (eg, viral URI, recurrent acute or chronic rhinosinusitis, vasomotor rhinitis, adenoid hypertrophy, and turbinate hypertrophy).

Viral URI can typically be differentiated from allergic rhinitis on the basis of acute onset of fever, purulent rhinorrhea, red swollen nasal mucosa, and sore throat. Nasal cytology will show a predominance of neutrophils, but this does not preclude an allergic component as well.

Recurrent acute rhinosinusitis often presents as viral URI that does not resolve after 10 to 14 days. Symptoms may overlap with mild allergic rhinitis, but typically patients have significant nasal obstruction and nocturnal cough. Protracted acute sinusitis may lead to a chronic low-grade infectious component or induce eosinophilic nonallergic rhinosinusitis. Nonallergic rhinitis with eosinophilia syndrome (NARES) is relatively rare in young children, but increases in frequency in older children. When NARES occurs, it may

be associated with nasal polyps and asthma, much like more severe allergic rhinitis. By definition, NARES patients have negative skin tests.

Vasomotor rhinitis describes a condition of nasal hyperresponsiveness to nonspecific irritant stimuli (eg, volatile organic compounds, perfumes, smoke, and pollutants). Affected patients have chronic nasal congestion that is typically minimally improved by environmental controls or medications (unless they have associated allergic rhinitis or rhinosinusitis). Children with isolated vasomotor rhinitis have normal nasal cytology, negative skin test results, and normal total and specific IgE test results, and they lack signs of associated atopic disease (eg, asthma or atopic dermatitis).

Nasal turbinate hypertrophy and adenoid hypertrophy represent important anatomic variants that cause chronic nasal obstruction. Ironically, both conditions may worsen in a child with significant allergic rhinitis, so allergic triggers should first be defined and aggressively treated with environmental controls and anti-inflammatory medications (eg, montelukast, nasal corticosteroids). Typically, children with significant nasal turbinate or adenoid hypertrophy are always congested and exhibit snoring. This congestion can lead to chronic serous otitis media, decreased hearing, decreased appetite, poor sleep pattern (including sleep apnea), and orthodontic abnormalities (high-arched palate, overbite, malaligned teeth).

Other less common conditions that can mimic some symptoms of allergic rhinitis include nasal foreign body, choanal atresia, rhinitis medicamentosa, cystic fibrosis, ciliary dyskinesia, and nasopharyngeal tumors.

## TREATMENT

Treatment of allergic rhinitis is initially based on history and physical examination, which provides a framework of likely triggers and clinical severity. Management includes allergen avoidance measures, pharmacotherapy, and occasionally immunotherapy. Therapy should be thoughtfully individualized based on the patient's age, unique environmental factors, symptom severity, and presence of associated medical conditions (eg, otitis media, sinusitis, asthma, and atopic dermatitis). If a child with perennial symptoms fails to respond to appropriate medication or if seasonal allergies become refractory to frontline therapy, consultation with a board-certified allergist should be considered. An allergist can help confirm the primary diagnosis, including identification of relevant allergic triggers; exclude other subtle upper and lower airway nonallergic diseases; fine-tune environmental control and pharmacotherapy; and, for select patients, prescribe allergen-specific immunotherapy.

Allergy treatment should always start with aggressive environmental controls. Although any exposure is important, controls should target the child's bedroom and any other areas where a fair amount of time is spent. When dust mite allergy is suspected, important measures include encasing the pillow, mattress, and box spring with dust mite-impervious covers, washing the bedding at least weekly in hot water, and minimizing stuffed animals or other dust collectors in

the bedroom. Ideally, animals should be removed if they are an important cause of symptoms, but this can be challenging for a family. Compromise measures include keeping the pet out of the bedroom at all times and, if feasible, washing the pet several times a month to help remove allergens that would otherwise end up throughout the home. If indoor molds are a concern, this is best remedied by decreasing moisture levels (eg, more effective exhaust fans in the bedroom and kitchen), installing double-pane windows, or using a dehumidifier. For children with pollen allergy, it is helpful to keep windows closed and use an air conditioner. In homes with forced-air heating and cooling, it can be helpful to install a filter that can remove all indoor allergens (<5 microns) and a humidifier or dehumidifier to maintain relative humidity in the 40% to 50% range. Keeping the humidity in this middle range provides a good compromise by discouraging dust mites, cockroaches, and mold growth at higher levels, but also avoiding the irritant effect of dry air at lower levels.

Primary pharmacotherapy for allergic rhinitis includes antihistamines (oral and nasal), leukotriene antagonists, and nasal corticosteroids. Adjunctive medications include decongestants, nasal cromolyn, nasal ipratropium, and oral corticosteroids.

Oral antihistamines are the first-line treatment for allergic rhinitis. These medications work by blocking histamine-1 receptors on mast cells, thus preventing rhinorrhea, sneezing, and itching caused by histamine. Recently developed antihistamines (eg, fexofenadine, cetirizine, levocetirizine, loratadine, and desloratadine) are typically effective with relatively low risk for side effects such as sedation. Although first-generation antihistamines such as chlorpheniramine, diphenhydramine, hydroxyzine, and triprolidine are also effective, their utility is often limited because of their sedative side-effect profile. Nasal antihistamines (eg, azelastine and olopatadine) represent an alternative approach to oral antihistamines, but also carry some risk for sedation because the medication is absorbed from the nose.

The leukotriene receptor antagonist montelukast is also approved for treating both perennial and seasonal allergic rhinitis. Montelukast is generally well tolerated and can be used as monotherapy or combined

with antihistamines. It can be particularly useful in children who have concurrent asthma or will not comply with the use of nasal sprays.

Nasal corticosteroids are the most effective monotherapy for treating allergic rhinitis, and some formulations have been approved for use in children 2 years and older. Available formulations include beclomethasone, budesonide, ciclesonide, flunisolide, fluticasone propionate, fluticasone furoate, mometasone furoate, and triamcinolone (Table 212-1). Growth suppression is a theoretical risk with nasal steroids, so the lowest effective dose should be used. Fortunately, several of the newer formulations have reduced bioavailability and are typically well tolerated.

Decongestants may be useful in the short term to help reverse the effects of acute congestion, but oral formulations carry a significant potential for causing irritability, hyperactivity, or sleep disturbances. The use of nasal decongestants should also be limited because prolonged therapy can actually induce rebound congestion (rhinitis medicamentosa). Nasal cromolyn sodium is well tolerated, but its use is limited because optimal efficacy requires use 4 to 6 times a day. Nasal ipratropium will help control rhinorrhea, but typically has little effect on other symptoms. Oral corticosteroids can be useful in the short term to help reduce acute severe allergic inflammation; in addition to providing symptom relief, these agents reduce nasal obstruction and nasal hyperresponsiveness and thus create a more favorable environment for the use of nasal therapy.

When allergic rhinitis does not respond adequately to environmental controls and appropriate pharmacotherapy, allergy consultation should be considered to clarify allergic triggers and exclude a nonallergic rhinitis component. If the diagnosis of moderate to severe allergic rhinitis is confirmed in this setting, allergen-specific immunotherapy becomes a consideration. Traditional allergy immunotherapy typically entails a 3- to 5-year series of subcutaneous injections in a controlled setting to help induce tolerance; such treatment is most effective for seasonal allergic rhinitis (pollen) and dust mite allergy, but may also have efficacy when animal dander and molds are an issue. Recently, sublingual allergy immunotherapy has become available to treat grass or ragweed allergy.

**Table 212-1** Nasal Corticosteroids

GENERIC NAME	TRADE NAME	CHILD DOSING	ADULT DOSING
Azelastine/fluticasone propionate	Dymista	1/nosril bid ( $\geq 12$ yr)	1/nosril bid
Beclomethasone	QNASL	NA	2/nosril qd
Budesonide	Rhinocort Aqua	1–2/nosril qd (6–12 yr)	1–4/nosril qd
Ciclesonide	Omnaris	1–2/nosril qd (6–12 yr)	2/nosril qd
Ciclesonide	Zetonna	NA	1/nosril qd
Flunisolide	(generic)	2/nosril bid (6–14 yr)	2/nosril bid–tid
Fluticasone propionate	Flonase (generic available)	1–2/nosril qd (4–12 yr)	1–2/nosril qd
Fluticasone furoate	Veramyst	1–2/nosril qd (2–11 yr)	1–2/nosril qd
Mometasone furoate	Nasonex	1/nosril qd (2–12 yr)	2/nosril qd
Triamcinolone	Nasacort AQ (generic available)	1/nosril qd (2–5 yr)	1–2/nosril qd ( $\geq 6$ yr)

*bid*, twice a day; *qd*, every day; *tid*, 3 times a day.

Sublingual treatment is started 12 weeks before the relevant pollen season and is continued on a daily basis through the season.

## PROGNOSIS

The prognosis for patients with allergic rhinitis is often related to environmental triggers, unique genetic factors, and willingness to comply with suggested treatment. Typically, children with perennial allergic triggers tend to have fewer problems as they get older. This is partially because environmental controls have an increased effect on indoor allergen exposure (dust mites, cockroach, animals, indoor molds), but also because these allergens tend not to induce much more IgE production over time. Accordingly, as the patient's airway gets bigger, the relative effect of these perennial factors tends to lessen—less congestion and less risk for otitis media, sinusitis, and asthma. In contrast, seasonal allergy caused by pollens tends to worsen over time because there is a predictable heavy exposure to each allergen every year that stimulates significant increases in specific IgE. These seasonal allergies can be positively modulated by changes in environment (moving), nasal corticosteroids, and allergen immunotherapy.

## WHEN TO REFER

Consider referral to a board-certified allergist in children with

- Persistent perennial rhinitis symptoms
- Poorly controlled seasonal rhinitis symptoms
- Recurrent otitis media, recurrent sinusitis, or worsening persistent or intermittent asthma
- Symptoms that warrant consideration of allergen-specific immunotherapy

## Chapter 213

# ALTITUDE SICKNESS

Eric C. Walter, MD, MSc; Andrew M. Luks, MD

## FOUNDATION

Because of a growing interest in adventure travel, increasing numbers of people are venturing to high altitude to partake in activities such as trekking, climbing, and sight-seeing. Because many of these trips occur in the setting of family vacations, it is likely that children will accompany their parents. As with adults, children who travel to high altitude are at risk for developing some form of acute altitude illness. This discussion considers the key environmental differences at high altitude and the basic physiologic responses to acute hypoxia and the acute altitude illnesses, including acute mountain sickness (AMS), high-altitude cerebral edema (HACE), and high-altitude pulmonary edema (HAPE). The emphasis throughout the chapter will be on risks associated with acute exposure and not issues related to long-term residence at high altitude.

High altitude is generally defined as elevations greater than 2,400 meters (~8,000 feet), although it should be noted that some important physiologic responses to acute hypoxia begin at elevations of about 2,000 meters (~6,000 feet). The defining feature of the environment at these and higher elevations is the decrease in barometric pressure relative to sea level. As a result, the inspired partial pressure of oxygen falls, leading to lower alveolar and arterial oxygen tensions. The fraction of inspired oxygen at 8,000 feet is still about 21%, but the decreased partial pressure makes it comparable to breathing 15% oxygen at sea level. In addition to hypobaric hypoxia, there are other important environmental changes at high altitude that should not be overlooked, including significant increases in ultraviolet exposure as well as decreased humidity and air temperature relative to lower elevations.

There are characteristic cardiopulmonary responses to the lower barometric pressures experienced at high altitude. Much of our understanding of these responses is derived from studies in adults, although more recent studies have included children and reported similar findings. The pattern of response is consistent across individuals, although the magnitude

of the observed responses is highly variable. The decreased arterial partial pressure of oxygen leads to an increase in minute ventilation (referred to as the *hypoxic ventilatory response*) as well as increases in heart rate and cardiac output. Arterial hypoxemia will also trigger an increase in serum erythropoietin concentrations that, over a period of days to weeks, leads to a rise in hemoglobin concentration. Decreased alveolar oxygen tensions cause hypoxic pulmonary vasoconstriction and a subsequent rise in pulmonary vascular resistance, which, in conjunction with the increase in cardiac output, leads to a rise in pulmonary artery pressure. Unlike the other responses described previously, hypoxic pulmonary vasoconstriction is not necessarily a beneficial response and may lead to complications in some individuals.

### ACUTE ALTITUDE ILLNESS

Individuals traveling to altitudes at or above 2,400 meters are at risk for developing 1 of 3 forms of acute altitude illness: AMS, HACE, and HAPE. AMS and HACE represent a spectrum of cerebral disorders, whereas HAPE is a pulmonary disorder. AMS is the most common high-altitude illness in adults and children but is not life threatening, whereas HACE and HAPE are much less common but represent serious and potentially life-threatening conditions.

### EPIDEMIOLOGY AND RISK FACTORS FOR ACUTE ALTITUDE ILLNESS

Between 24% and 61% of adult travelers to high altitude are affected by AMS, and children seem to be at equal risk. The prevalence of HACE in children is unknown, but it rarely occurs. The prevalence of HAPE in children is also not well known. A study of lowland children who traveled to the Tibetan plateau reported a prevalence of HAPE of 0.7% to 1.5%, similar to the reported prevalence in adults (0.2%–6%). However, re-entry HAPE, a form that occurs among high-altitude residents who return to high altitude after travel to lower elevations, may be more common among children than adults.

The primary risk factor for the development of acute altitude illness is an overly rapid ascent to too high an elevation, with the altitude at which someone sleeps being a more important determinant of risk than the highest altitude they may reach during the day. Other risk factors include a history of high-altitude illness, obesity, and overexertion. Good physical condition is not thought to protect against altitude illness. Pre-existing respiratory infections have been associated with an increased risk for HAPE in children. However, it is unclear whether this association is spurious; it may be explained by the increased frequency of viral infections in children compared with adults. Preexisting pulmonary hypertension and Down syndrome may be risk factors for HAPE in children as well.

### CLINICAL SYNDROMES OF ACUTE ALTITUDE ILLNESS

The clinical features of the various forms of acute altitude illness are summarized in Table 213-1. AMS usually occurs within 4 to 10 hours after arrival at

elevations at or above 2,400 meters, although the elevation at which symptoms begin varies among individuals. It is defined by the presence of headache plus 1 or more of the following symptoms: anorexia, nausea, vomiting, insomnia, dizziness, lassitude, or fatigue, in a person who recently arrived at altitude. Diagnosis is based solely on reported symptoms, and there are no characteristic physical examination findings or laboratory abnormalities. When individuals develop evidence of neurologic dysfunction, they are thought to be developing HACE. From a pathophysiologic standpoint, HACE is likely the same disease as AMS but at opposite ends of the spectrum of severity. HACE typically occurs in people with preceding AMS and usually progresses over hours to days. Characteristic signs include ataxia or evidence of altered mental status, including confusion, hallucinations, or drowsiness and, in severe stages, coma. Focal neurologic symptoms may be present but are not as common as signs of global encephalopathy. Abrupt symptom onset, focal neurologic deficits, and meningeal signs are rarely seen in HACE, and their presence should prompt consideration of other diagnoses. When HACE is not recognized and treated promptly, patients can progress to somnolence, coma, and death because of brain herniation.

HAPE is a potentially fatal form of noncardiogenic pulmonary edema typically seen in unacclimatized lowlanders 2 to 4 days after ascent to 2,400 meters or higher. The underlying pathophysiology differs significantly from AMS and HACE, with the primary mechanism being an overly large rise in pulmonary artery pressure on acute exposure to hypoxia. Elevated pulmonary artery pressure leads to an increase in hydrostatic pressures and subsequent leakage of protein and fluid from the vasculature into the interstitial and alveolar spaces. Early symptoms include decreased exercise performance, increasing dyspnea on exertion, and dry cough. As the disease progresses, individuals develop dyspnea with simple activities, such as walking on flat ground, and profound fatigue. Very late findings indicative of severe disease include cyanosis, respiratory distress, and a cough that produces pink or bloody sputum.

### DIAGNOSIS OF HIGH-ALTITUDE ILLNESS

The diagnosis of AMS is based on presenting symptoms and signs and does not require laboratory testing. The Lake Louise Scoring System (LLSS) is a validated scoring system for diagnosing AMS in adults (Box 213-1).

The LLSS asks 5 questions related to headache, gastrointestinal symptoms, fatigue, dizziness, and sleep-related symptoms. It is probably reliable in older children; however, younger children may have difficulty understanding the questions. Among children aged 4 to 10 years, for example, the LLSS underestimated the frequency of AMS symptoms compared with a scoring system using age-appropriate communication. To address this problem, the Children's Lake Louise Score (CLLS) has been developed for children younger than 3 years. Adapted from the LLSS, the CLLS replaces the headache score with a fussiness

**Table 213-1** Clinical Characteristics of Acute Altitude Illness

ALTITUDE ILLNESS	RISK FACTORS	SIGNS AND SYMPTOMS	TREATMENT	PREVENTION
AMS	Individual susceptibility; rate of ascent, absolute elevation gained, final elevation	Headache or unexplained fussiness with nausea, vomiting, anorexia, dizziness, or sleep disturbances in a child who recently arrived at altitude	Mild to moderate illness: rest, analgesics or antiemetics; may consider acetazolamide Severe illness: descent, oxygen, acetazolamide or dexamethasone	Gradual ascent; avoid overexertion; spend a night at an intermediate altitude; consider acetazolamide if slow ascent not possible or in children with a history of AMS. If AMS is mild, waiting 1-2 days for spontaneous recovery before descending is reasonable
HACE	Individual susceptibility; rate of ascent, absolute elevation gained, final elevation	AMS symptoms that progress to confusion, hallucinations, ataxia, altered mental status, or rarely focal neurologic deficits	Immediate descent and oxygen; dexamethasone (should not be used in lieu of descent and oxygen). If descent not feasible and oxygen not available, portable hyperbaric chamber	Gradual ascent; avoid overexertion; acetazolamide may prevent HACE by preventing AMS
HAPE	Individual susceptibility; rate of ascent, absolute elevation gained, final elevation; preexisting pulmonary hypertension or certain congenital anomalies (eg, absent pulmonary artery); preceding respiratory illness	Early: decreased exercise tolerance, progressive dyspnea on exertion, dry cough; tachypnea; hypoxemia Late: dyspnea with simple activities, profound fatigue, productive cough with pink or frothy sputum; cyanosis, severe hypoxemia	Immediate descent and oxygen; nifedipine may be considered in settings without access to medical services and if symptoms are not improving with descent and oxygen. If descent not feasible and oxygen not available, portable hyperbaric chamber	Gradual ascent; avoid overexertion; nifedipine for those with a prior history of HAPE or known predisposing condition

AMS, acute mountain sickness; HACE, high-altitude cerebral edema; HAPE, high-altitude pulmonary edema.

score. A pediatric symptom score (see Box 213-2) is also calculated based on the child's eating, activity, and sleep. The fussiness and pediatric symptom scores are totaled, and AMS is diagnosed if the total CLLS score is 7 or greater. Although there is no gold standard for comparison, the CLLS has been shown to have excellent interobserver agreement between parents in terms of classifying whether or not a child has AMS. Caregivers and physicians must be aware, however, that diagnosing AMS in children is complicated. Children often report AMS symptoms at baseline or with changes in their routine (such as traveling) without gaining elevation. Therefore, rather than relying solely on symptom scores, caregivers and physicians should have a low threshold to diagnose AMS in a child who has recently arrived at altitude. When a child has symptoms such as a change in behavior, fussiness, headache, poor appetite, or sleep disturbances that cannot be explained by an alternative diagnosis, AMS should be considered.

Caregivers should also be aware that difficulty breathing, cough, cyanosis, altered mental status, and other neurologic abnormalities are not part of AMS. The presence of any of these symptoms should prompt consideration of HACE or HAPE. HACE is usually preceded by AMS. Like AMS, HACE is a clinical diagnosis, and formal diagnostic tests, such as a head computed tomography scan, are not necessary. HACE can be fatal if not recognized and treated promptly. If any neurologic signs are present, treatment should be initiated immediately.

The diagnosis of HAPE is also largely clinical and should be considered in the presence of declining exercise performance, increasing dyspnea on exertion and at rest, or profound fatigue and cyanosis. In the field, pulse oximetry may be the only diagnostic tool available; the key finding is decreased oxygen saturation relative to asymptomatic individuals at the same elevation. When interpreting pulse oximetry values, it is important to consider that normal oxygen saturations

**BOX 213-1 Lake Louise Scoring System (LLSS)****HEADACHE**

- 0: No headache
- 1: Mild headache
- 2: Moderate headache

will be decreased at altitude and that there is considerable individual variability in observed normal values. Most healthy children have oxygen saturations greater than 90% at 2,500 meters (8,200 feet) and greater than 85% at 3,200 meters (10,500 feet). For individuals who have access to health care facilities, such as a clinic in a ski resort community, pulse oximetry can be supplemented with chest radiography to confirm the presence of parenchymal opacities. The presence of a normal chest radiograph should prompt consideration of an alternate diagnosis.

**MANAGEMENT**

The mainstay of treatment for high-altitude illness is descent to lower elevation. Mild to moderate AMS can be treated conservatively while remaining at the same elevation, although if symptoms do not improve with appropriate measures over several hours to 1 day, descent is indicated. If symptoms are worsening, descent should be considered sooner. Mild AMS may be treated with rest and hydration. Hydration does not treat AMS per se but does eliminate any element of dehydration that can mimic AMS. Symptomatic pharmacologic treatment options include antiemetics or analgesics such as acetaminophen (avoid aspirin in children). Oxygen is also effective. Because the natural history of AMS in children is not well understood, children with moderate to severe AMS should be treated cautiously. Descent and oxygen remain the best options. In addition to symptomatic therapy, children may be started on acetazolamide. Treatment for 48 hours is usually sufficient to relieve symptoms. The most common adverse reactions in adults are paresthesia and taste alterations. Although not studied, these are likely to be the most common reactions in children as well. Acetazolamide is a diuretic; therefore, there is a theoretical risk that children who are continent may have daytime accidents or bedwetting. Acetazolamide contains a sulfonamide, and although the risk for cross-reactivity and anaphylaxis in someone with a sulfa allergy is low, its use in a child with a sulfa allergy is contraindicated. Acetazolamide is contraindicated in pregnancy (class C) but can be used by nursing mothers. Dexamethasone is a suitable alternative treatment for severe AMS in children with a sulfa allergy or in extreme situations in which oxygen is not available and descent is not possible. Table 213-2 lists recommended doses for medications used to treat acute altitude illness in children.

The most important treatment for HACE or HAPE is descent to a lower altitude. If descent is not feasible, the child should be treated with supplemental oxygen or placed in a portable hyperbaric chamber (Gamow bag). These measures should not be delayed. Pharmacologic treatment should only be used in emergent situations in which neither descent nor oxygen is feasible or if the child is not improving with oxygen or descent. Children with HACE can be treated with dexamethasone, although its use for this purpose has not been studied in this patient population. Children who develop HAPE may be started on nifedipine, although this also has not been studied in this age group. The decision to use this therapy should reflect the setting in which HAPE occurs. Its use is reasonable when HAPE develops in a remote area away from

**Table 213-2** Recommended Pediatric Dosages for Medications Used in the Prevention and Treatment of Acute Altitude Illness

MEDICATION	INDICATION	ROUTE	DOSAGE
Acetazolamide	AMS prevention	Oral	1.25 mg/kg/dose every 12 hr (max 125 mg/dose)
	AMS treatment	Oral	2.5 mg/kg/dose every 8 to 12 hr (max 250 mg/dose)
Dexamethasone	AMS, HACE prevention	Oral	Should not be used for prophylaxis
	AMS, HACE treatment	Oral, IV, IM	0.15 mg/kg dose every 6 hr
Nifedipine	HAPE prevention	Oral	0.5 mg/kg/dose every 4 to 8 hr <sup>a</sup>
	HAPE treatment <sup>b</sup>	Oral	0.5 mg/kg/dose every 4 to 8 hr

AMS, acute mountain sickness; HACE, high-altitude cerebral edema; HAPE, high-altitude pulmonary edema; IM, intramuscular; IV, intravenous.

<sup>a</sup>For children weighing less than 20 kg, liquid-filled capsules (10 mg/0.34 mL) can be punctured. For children weighing more than 60 kg, the adult dosing regimen can be used (30 mg of sustained release formulation orally every 12 hours).

<sup>b</sup>Although the use of tadalafil, a phosphodiesterase inhibitor, for treatment of HAPE has been documented in adults, it has never been systematically studied in this regard and should not be used in children for this purpose.

medical resources, but for children who can access health facilities, it may not be necessary if the child is responding appropriately to supplemental oxygen or descent. The treatment dose for nifedipine has been extrapolated from adult data (Table 213-2).

## PLANNING AND PREVENTION

With proper planning and prevention, most children will enjoy high altitude without problems. Proper planning involves considering the child's age, medical history, and availability of medical services while at altitude. Equally important are the rate of ascent, elevation of the destination, and duration of exposure at altitude. Healthy children older than 4 to 6 weeks probably do not need any specific medical evaluations before traveling. However, neonates and those with preexisting illnesses should be evaluated by their physician before traveling to high altitude. Neonates are in transition from fetal to adult circulation. During this transition, they are particularly susceptible to the hypoxia associated with high altitude. Hypoxic pulmonary vasoconstriction may cause right-to-left shunting through a still patent foramen ovale or ductus arteriosus, leading to severe hypoxia. Full transition to adult circulation may take up to 3 months, but infants born at sea level will likely have a stable transition by 4 to 6 weeks. Children with cardiopulmonary disease should be evaluated carefully. At high altitude, hypoxemia may worsen in children with cystic fibrosis or other chronic lung diseases. Hypoxemia and shunting may also worsen in children with congenital heart disease. Children with Down syndrome or congenital heart disease associated with pulmonary hypertension may be at higher risk for HAPE. Depending on the severity of these diseases, travel to high altitude may not be advised. The risks and benefits of traveling should be carefully considered for any child who uses supplemental oxygen at baseline or had recent need for this therapy. Children currently on oxygen therapy may need to increase flow rates while at altitude. These children should be evaluated before traveling and may benefit from a high-altitude simulation test to determine how much additional oxygen may be needed.

Caregivers should consider the availability of medical services and rescue support at their intended destination and should strongly consider purchasing travel insurance, particularly when traveling with children with underlying medical problems. The risks of travel to destinations with easy access to medical care are much different than of travel to remote locations. Decisions about which high-altitude locations are safe and appropriate for children should be made on a case-by-case basis. However, a higher degree of caution is necessary with planned travel to remote locations without easy access to medical services or rescue, and these locations may not be appropriate for all children.

A gradual ascent, allowing the body to acclimatize to high altitude, is the single most important factor in diminishing the risk for AMS, HACE, and HAPE. In many cases, travel plans can be moderated to help minimize the risk. For example, families traveling from sea level to a Colorado ski resort could choose to spend the first night in Denver (~1,600 meters) before ascending to higher elevations for the rest of the vacation. At higher elevations (>3,000 meters), it is recommended that individuals not increase their sleeping elevation by more than 500 meters per night. Also, every 3 to 4 days, or with any overly large increase in the sleeping elevation, individuals should sleep at the same elevation for a second night. Although this approach has never been rigorously tested in controlled studies, it is generally accepted.

If a rapid ascent is unavoidable (eg, flying into Cuzco, Peru [~3,400 meters] on a trip to Machu Picchu), or if a child has a history of altitude illness, pharmacologic prophylaxis should be considered. Acetazolamide is the standard prophylactic agent for AMS. It should be started 24 hours before ascent. Use can be discontinued on descent to a lower altitude or, for children who will remain at altitude, 48 hours after arrival to the target altitude. Prophylaxis for HAPE should only be considered in children with a history of HAPE or a condition known to predispose to this disorder (eg, Down syndrome with pulmonary hypertension). Although its use has not been studied in children, nifedipine is the recommended agent for prophylaxis of HAPE.

## ADDITIONAL RISKS OF HIGH ALTITUDE

Ultraviolet light exposure is increased at high altitude and increases the risk for sunburns and ultraviolet keratitis. This risk is present even in cloudy conditions and is particularly high when individuals are traveling on snow or water because both increase the amount of reflected light. Caregivers should apply sunscreen frequently and liberally (sun protection factor  $\geq 30$ ) and ensure children have adequate head, eye, and lip protection at all times. Long sleeves, hats, and sunglasses should also be used. Because of lower humidity and air temperature, the risks for dehydration, hypothermia, and frostbite are also increased at altitude. Children are at higher risk than adults for these complications because they have a higher ratio of body surface area to body mass, resulting in proportionally higher fluid and heat losses. Children should be encouraged to drink plenty of fluids. It may be helpful to bring some favorite foods and drinks to ensure adequate food and liquid intake because altitude may affect the child's appetite and travel can disrupt the usual feeding schedule. Furthermore, in some locations the local diet may not be familiar to the child. To prevent cold exposure, adequate clothing is needed. Children who are carried may need extra layers because they are not generating as much heat as their caregivers who are exerting themselves. Layered clothing is recommended to allow for changes in weather and comfort.

## ONGOING CARE

Because a prior history of high-altitude illness is a risk factor for recurrence, any child who experiences high-altitude illness should be evaluated by a physician. A history of mild AMS may be preventable in the future with counseling of the importance of a slow ascent. If this is not possible, prophylactic treatment may be indicated before the next trip. A history of life-threatening illnesses such as HAPE or HACE should prompt a discussion about the risks and benefits of returning to high altitude. Given the high prevalence of undiagnosed chronic pulmonary hypertension and other cardiopulmonary abnormalities in children diagnosed with HAPE, these children should be screened for possible pulmonary hypertension or occult congenital heart defects. Children with a history of HAPE should be advised to not return to altitude if they have a current or recent viral illness.

## SUMMARY

Access to high altitude has become easier than ever, and more children are traveling to high altitude. Most children can travel to altitude safely, and known risks can be minimized with appropriate pretravel planning. Caregivers should be counseled regarding the recognition, prevention, and treatment of acute altitude illness as well as other risks not related to hypobaric hypoxia, including sunburn, dehydration, and hypothermia. Emphasis should be placed on the role of gradual ascent in preventing these illnesses and the central role descent plays in the treatment of severe disease.

## Chapter 214

# AMBLYOPIA AND STRABISMUS

Leonard B. Nelson, MD; Brandon Johnson, MD;  
Mary O'Hara, MD

## DEFINITIONS

*Amblyopia* is decreased visual acuity in the absence of an ocular structural disorder of the visual pathway.

*Strabismus*, an important cause of amblyopia, is a misalignment of the eyes that may be manifest at distance or near, constant or intermittent, and may be present in any field of gaze.

Many times, parents will note strabismus and bring it to the attention of the pediatrician. Amblyopia, however, is more commonly discovered via screening tests such as visual acuity testing or red reflex testing in the preliterate child. Both conditions warrant referral to an ophthalmologist for further care.

*Orthophoria* is normal eye alignment in which both eyes are simultaneously directed at an object of regard (Figure 214-1).

*Heterophoria* is an ocular misalignment that is latent and only occurs with stress, fatigue, and other conditions that may interrupt fusion of an image. Large heterophorias can cause bothersome symptoms such as intermittent diplopia and eye strain (asthenopia).

*Heterotropia* is a manifest misalignment of the eyes, present at all times. When the visual axis of the deviated eye is directed inward (toward the nose), *esotropia* is present (Figure 214-2). *Exotropia* is present when the visual axis of the deviated eye is divergent or directed outward (Figure 214-3). Likewise, *hypertropia* describes an eye deviated upward and *hypotropia* an eye deviated downward. The latent (not present at all times) counterparts of these deviations are described as *esophoria*, *exophoria*, *hyperphoria*, and *hypophoria*.

Strabismus is *comitant* when the deviation is the same in any direction of gaze and *incomitant* when it varies with direction of gaze. *Monocular* strabismus describes a preference to fixate consistently with the same eye, whereas *alternating* strabismus implies no ocular preference with fixation shifting from one eye to the other. Any strabismus present by age 6 months

**Figure 214-1** Orthophoria: Note the centered corneal light reflexes.

**Figure 214-2** Esotropia: Note the laterally misplaced corneal light reflexes.

**Figure 214-3** Exotropia: Note the medially displaced corneal light.

is defined as *infantile* and all other deviations are *acquired*. Finally, a deviation that is the same whether fixation is at distance or near is said to have a normal accommodative convergence (AC) to accommodation (A) ratio (AC/A). A *high* AC/A implies that convergence with accommodation is excessive so that an esotropia is greater at near fixation than distant fixation, whereas a *low* AC/A ratio implies that convergence with accommodation is deficient.

## EPIDEMIOLOGY

Amblyopia has a frequency ranging from 1.3% to 3% in preschool and school age children. The prevalence in the general population is between 2% and 2.5%.

Strabismus, a common cause of amblyopia, affects between 2% to 5% of preschool children. Esotropia is the most common type of ocular deviation in the

**Figure 214-4** Pseudoesotropia: Esotropic appearance because of epicanthal folds, which obscure the medial sclera of the right eye. Note the corneal light reflexes are centered, indicating orthophoria.

pediatric population, representing more than 50% of cases.

## ETIOLOGY

Amblyopia develops early in childhood when there is aberrant development of the visual system. In a series of landmark studies, Hubel and Wiesel revealed the role of visual stimulation in shaping the architecture of the cortical visual pathway. By depriving kittens of the use of one eye during the “critical period” of visual development, they showed that input to the visual cortex became dominated by signals from the functioning eye. Normal binocular vision develops only when clear and focused images project onto corresponding areas of both retinas. If the image from one eye is distorted or misaligned during the critical period of cortical pathway development, input from that eye is decreased and amblyopia is the consequence. Although amblyopia more commonly occurs in a unilateral fashion, it can be bilateral. The different causes of amblyopia will be discussed under Classification. Strabismus is one of the most common causes of amblyopia and may be congenital or accommodative, or occur as a feature of several syndromes.

## DIAGNOSIS

### Differential Diagnosis

In the condition known as *pseudostrabismus*, the visual axes are aligned accurately, but there is a false appearance of strabismus because of prominent epicanthal folds; a flat, broad nasal bridge, or a narrow interpupillary distance. This “optical illusion” occurs because one or both eyes seem to turn inward when a smaller amount of white sclera is observed nasally than would be expected. Pseudoesotropia (Figure 214-4) is a very common condition prompting referral to a pediatric ophthalmologist.

### Diagnostic Approach

#### Strabismus

Pseudostrabismus is differentiated from true strabismus by observation of the corneal light reflex, which is symmetrical in both eyes when the eyes are aligned properly. In addition, the cover/uncover test is used to determine whether a true strabismus is present: on cover/uncover testing, a refixation movement indicates a true strabismus.

### Amblyopia

Amblyopia can be detected by identifying a difference in visual acuity between the two eyes, generally greater than 2 lines on the eye chart. The “crowding phenomenon” is a characteristic of amblyopia wherein the visual acuity measurement is better if tested with single, isolated symbols instead of a group of symbols. This improved visual acuity with single-symbol testing can be useful in distinguishing amblyopia from loss of vision secondary to other causes because children with nonamblyopic vision loss have equally poor vision when tested with one versus a group of symbols.

Amblyopia can be detected in children unable to perform subjective visual acuity testing (generally <3 years of age) by evaluating their fixation behavior with occlusion. A child with an amblyopic eye will object to occlusion of the nonamblyopic eye. This technique is also useful in children with strabismus. A strabismic child who spontaneously alternates fixation is unlikely to have amblyopia in either eye, whereas a child who consistently turns one eye is likely to have amblyopia in the deviated eye. If occlusion of the “straight” eye results in wandering fixation or lack of visual interest, suspect amblyopia.

Recently, instrument-based visual screening was developed to screen children younger than 5 years of age for risk factors of amblyopia. Photoscreeners, autorefractors, and other instruments are used to detect the presence and magnitude of ocular conditions that can lead to amblyopia. Instrument-based visual screening is quick and requires minimal cooperation from the child. However, it must be administered and interpreted by appropriately trained individuals and does not replace vision acuity testing in the literate child.

### Classification

#### Amblyopia

Amblyopia is classified according to the underlying ophthalmic condition that is causing abnormal binocular interaction or interruption of a clear image projected onto the retina. Conditions that result in amblyopia include strabismus, significant refractive errors, anisometropia (difference in the refractive error between the two eyes), and visual deprivation from occlusion or obscuration of the visual axis.

*Strabismic amblyopia* results from improper alignment of the eyes, causing a disruption of the binocular fixation required for normal visual development. If the child strongly favors the aligned eye, amblyopia will likely develop in the deviated eye.

*Refractive amblyopia* can occur in eyes with very large or sometimes even small degrees of hyperopia (farsightedness), myopia (nearsightedness), or astigmatism (irregular corneal curvature). Children at greatest risk of developing refractive amblyopia have refractive errors greater than 4.5 diopters (measure of optical lens power) of hyperopia or 2.5 diopters of astigmatism. Conditions such as ptosis (lid drooping) and orbital tumors can mechanically change the shape of the cornea and thereby induce an astigmatism, leading to refractive amblyopia.

*Anisometropic amblyopia* is a subcategory of refractive amblyopia. Anisometropia is unequal refractive error between the two eyes. If the difference in refractive error is more than 1.5 diopters of hyperopia or astigmatism, or 3.0 diopters of myopia, amblyopia is likely to develop in the eye with the greater refractive error.

*Visual deprivation amblyopia* results from any abnormality in the visual axis preventing the formation of a clear, focused image on the retina during the period of visual development. Corneal opacities, congenital cataracts, and vitreous hemorrhage can blur the visual axis and induce amblyopia.

### Strabismus

*Infantile esotropia* (formerly called congenital esotropia) is by definition an esotropia present by 6 months of age. It is not unusual for variabilities in alignment to occur during the first few weeks of life, but they usually clear by 2 or 3 months of age. In children with infantile esotropia, the misalignment continues after 6 months of age, is often readily apparent, and measures greater than 30 prism diopters (measure of deviation). Affected children usually alternate fixation and have good vision in both eyes. However, a preference to fixate with one eye may indicate poor vision in the nonfixating eye, which must be treated to prevent amblyopia. These children often have a refractive error that is in the normal range for young children.

- *Cross fixation* is often present and indicates that the child is looking at the left visual field with the right eye and the right visual field with the left eye, giving the appearance of a bilateral abduction defect (such as occurs with cranial nerve VI) in which neither eye seems able to turn outward.
- *Inferior oblique overaction*, seen in 72% of children with infantile esotropia, is an upswing of the eye when it is in the adducted position.
- *Dissociated vertical deviation*, characterized by elevation and excyclotorsion (outward, rotational movement) of the nonfixating eye, is present in 46% to 90% of children with infantile esotropia.

*Accommodative esotropia* occurs when a child's large accommodative reserve (focusing power) is linked to an abnormally large convergence (inward eye movement), causing an esotropia when focusing. Children with large hyperopic refractive errors are at particular risk. Onset is, on average, at 2.5 years but can range from 6 months to 7 years. The deviation, which may begin intermittently, can eventually become constant, independent of fixation distance and spectacle correction. If the child develops a fixation preference, amblyopia may develop.

*Constant exotropia*, a constantly present out-turning of the eye, can be congenital or can result from decompensation of an intermittent exotropia. It can also occur after significant loss of vision in one eye (usually after 5 years of age), or can occur from overcorrection following muscle surgery for esotropia.

*Intermittent exotropia*, the most common type of divergent strabismus in children, is characterized by an outward drifting of one eye, usually at distance fixation. Visual acuity is usually good and binocular vision maintained because the eyes initially can be

kept straight most of the time. Intermittent exotropia tends to occur between infancy and 4 years. The consensus among pediatric ophthalmologists is that the frequency and magnitude of deviation with intermittent exotropia will not improve with time, and affected children are at risk for decompensating into constant exotropia. Children with this condition should be evaluated early by an ophthalmologist to monitor progression.

*Paralytic strabismus* occurs when paralysis or paresis of an extraocular muscle causes a motor imbalance, resulting in a deviation that varies with the direction of gaze and fixation with the involved or uninvolved eye (noncomitant deviation). The diagnosis is suggested by detecting deficient eye movement in the field of action of the paretic muscle. Newly acquired double vision and an increase in deviation with fixation of the paretic eye can also suggest paralytic strabismus.

- *Third cranial nerve palsy* is more commonly congenital than acquired. When congenital, the cause is generally either a developmental anomaly or birth trauma. Acquired third cranial nerve palsy requires immediate evaluation because it may result from a brain aneurysm or tumor. Blunt trauma, infection, and ophthalmic migraine can also cause an acquired third cranial nerve palsy. It is prudent to perform imaging of the basal structures, including the orbit on a child with a nontraumatic, acquired third nerve palsy. Examination findings consistent with the diagnosis are exotropia, hypotropia, and ptosis of the upper lid. Pupillary dilation can also be present if the parasympathetic fibers of the third nerve are affected. The child will have difficulty with adduction (inward eye movement), elevation, and depression of the affected eye. Aberrant regeneration of the nerve fibers can result in adduction of the eye on attempted upgaze or downgaze and retraction of the upper lid on downgaze (pseudo-Graefe sign).
- *Fourth cranial nerve palsy* is either congenital or, if acquired, secondary to head trauma. Palsy of the fourth nerve results in weakness of the superior oblique muscle, which causes the child to tilt his head to the opposite shoulder in an attempt to compensate for the vertical deviation of the eye. Correction of this abnormal head posture requires addressing the ocular misalignment.
- *Sixth cranial nerve palsy*, which results in weakness of the lateral rectus muscle, is rare in its congenital form but can occur transiently in newborns, with resolution by 6 weeks of age. It is important to evaluate affected children for congenital esotropia and for disorders resembling sixth nerve palsy such as Duane retraction syndrome and Moebius syndrome. Acquired forms of this palsy result most commonly from trauma, and also from meningitis, hydrocephalus, and a variety of brain tumors, in particular medulloblastomas, brainstem gliomas, and posterior fossa astrocytomas. Rarely, sixth nerve palsy can follow a nonspecific febrile illness or upper respiratory infection. The palsy generally starts 1 to 3 weeks after the illness and begins to improve within 3 to 4 weeks, with

complete resolution by 10 weeks. Gradenigo syndrome is a condition in which the sixth nerve is pinched against the petrosphenoid ligament (Gruber ligament) as the nerve passes between the ligament and the dura (Dorello canal). This can occur secondary to otitis media, mastoiditis associated with petrositis and edema of the dura, or venous sinus thrombosis. Antibiotic treatment is effective in limiting the duration of palsy to 3 to 6 weeks. Whatever the cause, abduction deficits and large esotropias in primary gaze are seen with sixth nerve palsy. Binocular vision can be maintained with lateral gaze away from the palsied eye, which results in a compensatory head turn toward the palsied eye. The greatest eso-deviation is observed in the field of action of the paretic lateral rectus muscle.

### Strabismus Syndromes

*Duane retraction syndrome* is characterized by the inability to abduct or adduct the affected eye(s) partially or completely. This results in restricted horizontal movement. In addition, when the eye attempts to adduct, the globe retracts and the palpebral fissure narrows. The oculomotor disturbance causing this syndrome seems to be the result of paradoxical innervation of the lateral rectus muscle. As a result, lateral gaze is poor from improper lateral rectus contraction, and adduction is also poor because of the dual contraction of the medial and lateral rectus muscles. The combined stimulation of the medial and lateral recti also acts to pull the globe into the orbit, causing globe retraction and narrowing of the palpebral fissure. This syndrome occurs twice as often in the left eye, and girls are more likely to be affected than boys by a 3:2 ratio. Affected children often have normally aligned eyes in the primary position throughout childhood, but some develop an increasing eso-deviation, which may lead to a compensatory head turn. If the esotropia is significant with a compensatory head turn, surgery is indicated.

*Brown syndrome* is typically a unilateral condition in which the ability to elevate the eye is limited in the up and in position. Elevation is usually normal when the eye is abducted. Often there is no abnormality in primary position, but sometimes the involved eye is lower. If this occurs, fusion can only occur in lateral gaze and, as a result, a compensatory face turn is assumed. The cause of Brown syndrome is a tight, relatively inelastic superior oblique muscle. This can be evaluated using a forced duction test: the child is examined under anesthesia and forceps are used to grasp the conjunctiva and underlying sclera. The eye is then mechanically moved to detect any movement restriction. In affected children, the test reveals restriction of elevation in the adducted eye. A superior oblique weakening procedure can be performed if a vertical deviation exists.

*Moebius syndrome* consists of lateral gaze paralysis, usually esotropia, and varying degrees of facial diplegia resulting from underdevelopment of the sixth and seventh cranial nerves. Although vertical rotations are often full, total ophthalmoplegia may be present. A wide variety of musculoskeletal anomalies

may occur, including pectoral muscle defects, brachial malformations, and clubfoot. Palsy of the tongue, a common associated defect, is often manifest during infancy by a poor suck reflex.

The eye findings in this condition are thought to arise from fibrotic and thickened extraocular muscles. Surgery is reserved for significant esotropia, but the range of horizontal eye movements does not tend to normalize.

*Double elevator palsy (monocular elevation deficit)* is a monocular deficit of elevation that occurs both in adduction and abduction, either from a paresis of the superior rectus and the inferior oblique muscles, both elevators of the eye, or possibly from fibrosis of the inferior rectus muscle. As a result, hypotropia is seen in the paretic eye and ipsilateral upper lid pseudoptosis may occur when the child fixates with the nonparetic eye. Once fixation is switched to the paretic eye, the nonparetic eye becomes hypertropic and the ptosis disappears. Surgery is helpful only if a vertical deviation in primary gaze exists; the surgery is performed with the intention of improving alignment.

*Cyclic strabismus* is a rare entity characterized by alternating 24-hour periods of misalignment and orthophoria, usually acquired in children 3 to 4 years of age and typically manifesting as an esotropia. Treatment is with surgery to correct the full deviation. Results are generally satisfactory and do not produce exotropia on the nonstrabismic day.

## MANAGEMENT

### Treatment Approach

In amblyopia, treatment is initiated to achieve equal and normal vision between both eyes. The likelihood of achieving this goal is greater if treatment begins at an early age.

Treatment is aimed at aligning eyes to help promote binocularity and prevent amblyopia. Surgery can also be performed to correct misaligned eyes that are socially unacceptable or cause an unwanted head posture.

### Specific Treatments

#### Amblyopia

In 40% of children with amblyopia, optical correction alone can adequately treat the amblyopia when there is a significant refractive error. However, the effect is not immediate; it requires prolonged and consistent wear of appropriate spectacle correction. If optical correction does not fully treat the amblyopia, penalization therapy may be needed in addition to glasses.

Penalization therapy is used in the treatment of amblyopia caused by nonrefractive conditions and in refractive conditions where glasses alone do not resolve the amblyopia. Penalization therapies usually involve occlusion or optical blurring of the nonamblyopic eye. Occlusion therapies include opaque adhesive patches that cover the eye completely (Figure 214-5). When used with spectacles, the adhesive patch should still be placed directly on the eye (Figure 214-6). Slip on, press on, or clip on occluders can also be used in children with glasses (Figure 214-6). Initial therapy involves

**Figure 214-5** Occlusive patch to treat amblyopia right eye.

several awake hours of occlusion daily. Follow-up appointments are made at routine intervals to monitor the success of treatment, help the parents work out patching difficulties, and assess for reverse amblyopia of the patched eye.

Children, especially those with very profound amblyopia, may not tolerate occlusion. If so, it is often helpful to institute patching progressively over the first week of treatment. Rarely, and only if necessary, mittens taped to hands, or devices that prohibit elbow flexion, may be used for short periods of time to prevent the child from removing the patch, allowing occlusion therapy the chance to be effective.

Optical blurring is another treatment modality for amblyopia. A cycloplegic eyedrop or ophthalmic ointment, usually atropine, is used to blur the sound eye at close range, causing fixation preference to switch to the amblyopic eye. Treatment schedules include daily use of atropine or, more recently, weekend use only, because the cycloplegic effects of atropine persist for several days after treatment. This technique is not effective when amblyopia is severe (visual acuity is poorer than 20/100 in the amblyopic eye) because atropine does not create enough reduction in visual acuity to switch the fixation preference.

Successful treatment depends on maintaining improved visual acuity until the age at which the child

**Figure 214-6** Occlusive patch and glasses to treat anisometropic amblyopia.

reaches visual maturity, generally considered to be 9 years of age. Recent studies demonstrated improvement in vision with amblyopia treatment in older children, indicating that the critical period until visual maturity may be prolonged in some individuals.

If visual acuity decreases after the cessation of penalization, ongoing therapy may be necessary to maintain improved visual acuity in the amblyopic eye. Maintenance therapy is instituted using part-time patching or a reduced cycloplegia schedule. Therapy is reduced gradually to the lowest level needed to maintain visual acuity. Routine scheduled follow-up is important in amblyopia treatment.

### Strabismus

Pseudostrabismus does not require treatment but should prompt a re-evaluation if there is any change in the alignment.

Treatment of infantile esotropia begins with correcting hyperopia with spectacles, if necessary, and penalization therapy if one eye has poor vision. The deviations are measured over serial examinations. If the misalignment persists despite treatment, and if the measurements are consistent, surgery is performed to correct the alignment.

Accommodative esotropia is managed by fully correcting the hyperopic refractive error, which reduces the need for accommodation and helps reduce the excessive convergence. If residual convergence occurs

at near fixation, bifocals can sometimes be used to reduce this residual accommodation. In the past, anticholinesterase miotics were used with or in place of glasses, because they constrict the pupil, induce ciliary spasm, and reduce the accommodative effort. These drugs can have significant side effects such as iris cysts, lens changes, and reduced plasma and red-cell cholinesterase, which limit their utility. They are used very rarely in the treatment of residual convergence. Muscle surgery is reserved for children who have significant residual deviation uncorrected by glasses. Although the prescription for glasses may change after surgery, glasses usually remain a necessary part of accommodative esotropia treatment.

Intermittent exotropia is managed with observation if the deviation is small and infrequent. Alternate patching or over-minus glasses that increase convergence by encouraging accommodation are also used. Large deviations or deviations that are increasing in frequency and threatening binocular function are treated with muscle surgery.

Constant exotropia is managed with amblyopia therapy if poor vision is present. Surgery is reserved for cases that cause psychosocial distress, with stable deviation measurements.

Third nerve palsy is treated with occlusion therapy if amblyopia is present. Poor vision may affect the contralateral eye if the patient prefers fixation with the palsied eye. After visual acuity is improved, surgery is considered to maximize range of motion and align the eyes in the primary position. Ptosis correction can be achieved surgically with a frontalis sling.

Fourth nerve palsy is managed with muscle surgery to improve alignment and eliminate abnormal head posture.

Sixth nerve palsy, when acquired, and in a child without a history of trauma or recent febrile illness, should be evaluated carefully for neurologic cause. If secondary to a febrile illness or trauma, the condition tends to resolve or at least improve considerably over time. Temporary improvement of alignment can be achieved with botulinum injections into the opposing medial rectus muscle. Surgery is indicated if a large deviation in primary position and a face turn are present after 6 months.

## ONGOING CARE

### Follow-up

Children being treated for amblyopia with penalization therapy need to be re-examined at routine intervals. The exact schedule is determined by the child's age and the manner of therapy. Younger children are reexamined more frequently than older children because of the increased plasticity of the younger cortical visual pathways. Even after the amblyopia is successfully treated, children need to be monitored for recurrence.

Children with strabismus also need to be followed for ongoing problems related to their strabismus. Visual acuity, binocular function, and refractive errors need to be addressed throughout childhood.

### Complications

Amblyopia complications are related to the loss of vision in one or both eyes. Complications of amblyopia therapy include reverse amblyopia. Penalizing the sound eye can result in amblyopia of that eye. Close follow-up by the ophthalmologist is required to detect this condition and treat it. Compliance to therapy can be problematic; parents need to be supported in their efforts to patch or atropinize their children. Contact dermatitis can develop from the adhesive material of an eye patch. Atropine is an anticholinergic drug and can cause high fevers and hyperactivity if absorbed systemically. These side effects can be mitigated by using pressure to occlude the punctum during installation in an effort to decrease absorption systemically through the nasolacrimal system. A recurrence of amblyopia can occur after the cessation of therapy. This usually occurs in the first 3 months after treatment concludes. Therefore, regularly scheduled follow-up appointments are important after penalization therapy ceases.

Complications of strabismus include amblyopia, decreased binocular function as manifest by decreased depth perception, or diplopia. Older children may develop psychosocial distress from their strabismic appearance. Complications of treatment include recurrent or residual strabismus and consecutive strabismus (misalignment in the opposite direction after strabismus surgery).

### Prognosis

The prognosis for amblyopia varies with the child's age and the type and depth of amblyopia. Younger children tend to respond more positively to treatment. Dense amblyopia is more difficult to treat successfully. The early treatment of amblyopia carries a more favorable prognosis.

The prognosis for strabismus depends on the type and duration of strabismus. In general, the earlier treatment is initiated, the better the prognosis.

## Chapter 215

## ANIMAL AND HUMAN BITES

Neil E. Herendeen, MD; Peter Szilagyi, MD, MPH

Estimates indicate that each year more than 4.5 million people across the United States are bitten by animals. Dog bites account for more than 90% of these injuries, and cat bites account for most of the remainder, with human bites accounting for less than 2%. Although wild animal bites are rare, they are potentially more serious, given the risk of rabies and other infections. One-half of all animal bites are trivial and require no medical treatment; only 10% are severe enough to require suturing, and 2.5% result in hospitalization. Bite wounds account for an estimated 1% of pediatric emergency department visits. Children experience the greatest number of animal bites (the peak age group is 5–14 years), with 50% of all school-aged children reporting an animal bite at some point in their lives. One-half of toddlers attending child care centers will experience 1 or more bites from a peer, but only 2% of those bites break the skin. With dog bites, adults are bitten on an extremity; children, however, are bitten primarily on the head or neck 75% of the time. Boys are twice as likely to be bitten by a dog, whereas girls receive twice as many cat bites. Not surprisingly, most of the animals live in the victim's neighborhood (75%) or home (15%); in most instances, the bites are provoked by humans.

The major morbidity from animal bites results from direct trauma and infection. Although dog bites are more likely to cause lacerations or avulsions, these open wounds can be debrided and cleaned to prevent infection. However, puncture wounds, which usually

**Table 215-1** Risk Factors for Infection in Animal Bites

RISK FACTOR	INFECTION RATES
Location of bite	Hand (18%–36%) > arm or leg (12%–16%) > face (5%–11%)
Type of wound	Puncture with laceration (17%–26%) > laceration alone (9%–12%)
Interval between bite and medical care	If >24 hr, risk of infection increases
Type of animal	Cat bites (40%–50%) Dog bites (10%–30%) Human bites (13%–40%)

do not require suturing, can result in deep-tissue infections.

As shown in Table 215-1, the risk of infection varies according to several factors. Hand wounds are most likely to become infected, partly because of the type of wound (most frequently a puncture wound), the relatively poor vascular supply, and the vulnerability of the closed spaces of the hand. If more than 24 hours elapses before medical attention is sought, then the risk of infection is greatly increased. Cat and human bites pose a greater risk of infection than dog bites, partly because these bites more often cause puncture wounds, whereas dog bites frequently cause open lacerations.

Most bacteria associated with bite wounds are common organisms that reside in the animal's oral cavity. Bacteria on the victim's skin may also contribute to infection. Most infections involve several pathogens, often both aerobes and anaerobes. *Pasteurella multocida*, a Gram-negative, facultative anaerobe found in the mouths of most dogs and cats, is highly associated with cat bite infections (up to 80%) and to a lesser extent with dog bite infections (up to 50%). Although the exact prevalence of other pathogenic bacteria isolated from infected animal bites varies, staphylococci, streptococci, *Moraxella*, and *Neisseria* are common.

Another group of Gram-negative bacteria, capnocytophaga, has frequently been isolated from dog bite wounds. Interestingly, human bites are rarely infected by *P. multocida* but are often associated with Gram-positive organisms, Gram-negative anaerobes, or *Eikenella corrodens*, a genus almost unique to human bites that in rare cases is found in cat bites. Human bites have the potential to transmit human immunodeficiency virus and the hepatitis B virus and should be evaluated in persons who are bitten by those at high risk for infection.

## EVALUATION

### History

Important points to elicit while taking the history of the wound include the length of time since injury, the type of animal (including domestic or wild), whether the attack was provoked or unprovoked, the animal's

present location, the child's immunization status and health, and prior wound management.

### Physical Examination

The physical examination entails a thorough musculoskeletal and neurologic examination to determine whether underlying structures were damaged and a thorough inspection of the wound for signs of infection. Special attention must be given to bites on the hand because, particularly in deep puncture wounds, superficial signs of infection (redness, swelling, purulent drainage) may be absent. Finally, the physician should be aware that deep infections of tendons or bones and systemic infections can occur if animal bites go untreated.

### Laboratory Evaluation

Gram stain of a wound specimen is not useful, because findings do not correlate with culture results. Cultures of clinically infected animal bite wounds are reported to have no growth in as many as one-third of cases; conversely, cultures of clinically noninfected bite wounds grow a wide spectrum of oral flora bacteria in the same proportion of cases. Moreover, such cultures do not predict the likelihood of subsequent infection, nor do results correlate with culture findings when clinical infection becomes apparent. However, cultures of clinically infected wounds may help ensure that the causative bacteria are sensitive to the antibiotic used. Radiologic studies of deep puncture wounds may be necessary to determine whether the periosteum has been penetrated. These studies include those of the calvaria of small children who experience bites to the head.

## MANAGEMENT

### Wound Care

The initial step in treating animal bites is meticulous wound care. This process involves gently cleaning the wound with soap and water and vigorously irrigating with saline solution. Saline irrigation of the wound with a syringe and a 19-gauge needle generates increased pressure on the tissues that facilitates cleansing of the wound and reduces the risk of infection. Devitalized tissue should be debrided. Puncture wounds should be cleaned, but irrigation is ineffective and may result in further damage to underlying structures. Elevation and immobilization are important for significant extremity injuries. The child's immunization status should be assessed and tetanus prophylaxis provided if indicated.

Primary closure of lacerations caused by animal (or human) bites is controversial. Wounds that are clearly infected should not be closed. The consensus is that most noninfected lacerations can be sutured, after meticulous cleansing and irrigation, for cosmetic purposes or for hemostasis, without increasing the risk of infection. Hand wounds may be an exception because of the great likelihood of infection and the risk of serious complications from deep, closed-space infections; in these cases, suturing is suggested only for large wounds.

The use of prophylactic antibiotics in noninfected animal bite wounds is controversial. Prophylactic antibiotic therapy reduces the risk of infection after human bites or animal bites of the hand; however, no evidence has been found that it is effective for other types of cat or dog bites. If infected, bite wounds brought to medical attention after 24 hours should then be treated with antibiotics. The choice of antibiotics depends on culture results or, if cultures are not available, on the likely pathogens. Although penicillin is active against *P multocida* and many oral flora, the addition of a penicillinase-resistant antibiotic provides more effective coverage. Amoxicillin/clavulanic acid is an excellent choice for the empirical treatment of bites from all animals. Patients with infected hand bites, those with moderate to severe infections at other bite sites, and those who present with systemic symptoms such as high fever should be treated with intravenous antibiotics (ampicillin-sulbactam). Penicillin-allergic children may be treated with an extended-spectrum cephalosporin or trimethoprim-sulfamethoxazole plus clindamycin. Doxycycline with activity against *P multocida* and MRSA provides another alternative in persons 8 years and older.

Infections

The time of the infection’s onset may be a clue to the cause of infection. Cellulitis from *P multocida* generally develops rapidly, within hours of the animal bite, whereas systemic signs (fever, lymphangitis) are usually absent. A cellulitis that develops gradually, over days, is more likely the result of Gram-positive cocci or other pathogenic bacteria.

The physician should remember that cat-scratch disease is a relatively common complication of cat bites and, less commonly, of bites by other animals. This disease often begins with the development of a red, painless papule at the site of a recent scratch or bite. Within weeks, a tender, enlarged, regional lymph node appears, usually associated with fever, malaise, and other systemic symptoms. This self-limited illness, which is caused by *Bartonella henselae*, can be diagnosed clinically or confirmed by serologic testing. Antibiotics offer minimal clinical benefit, and because the disease is self-limited, their use seldom is indicated. Large, tender, fluctuant lymph nodes may require aspiration or incision and drainage.

Wild Animal Bites

Animal bites from nondomestic animals require special attention. Although most primary care physicians will never treat a child who has rabies, they will evaluate children who may have been exposed to it. With the increasing spread of rabies among nondomestic animals, the number of people exposed to rabies and requiring vaccination is increasing dramatically. A full postexposure vaccination series can cost \$2,000 or more and requires 4 visits to the physician in a single month. Knowing when and whom to treat requires an understanding of rabies transmission and its epidemiologic mechanism. Rabies is an RNA virus present in saliva and transmitted by bites or by licking of the mucosa or open wounds. In the United States, in all cases of rabies resulting from a dog or cat bite, the infected animal has been noted to become ill during the standard 10-day confinement and observation period. Thus, location, confinement, and observation of the animal are important.

In cases involving wild animal bites, consultation with the local health department is helpful in determining the risk of rabies in a specific animal for a particular geographic region. In general, bats, skunks, foxes, raccoons, and other carnivores are considered rabid until proved otherwise by laboratory tests; in the interim, or if the animal cannot be found, treatment with human rabies immunoglobulin (HRIG/RIG) and human diploid cell vaccine is suggested. Current recommendations call for most, if not all, of the HRIG/RIG dose (20 IU/kg of body weight) to be infiltrated in and around the site of the bite. Rabies prophylaxis is now also suggested after exposure to bats in a confined setting, such as finding a bat in the bedroom on awakening, even when no bites are visible. Because the location of a bat bite is rarely known, the total HRIG/RIG dose may be given in the thigh. If the bat can be captured and submitted for testing, then rabies prophylaxis can be avoided in 60% of the cases (Table 215-2). Rabies, which was previously considered a fatal disease, has been treated with the induction of a coma (Milwaukee protocol); however, severe neurologic sequelae remain.

A variety of rare diseases have been described after wild animal bites; consultation with the local health department may help in establishing the diagnosis and managing treatment. Rat-bite fever, a systemic illness

Table 215-2 Rabies Vaccination Guidelines	
ANIMAL	MANAGEMENT
Wild carnivores	Begin HRIG/RIG and HDCV. Submit animal’s head for testing.
Healthy domestic dogs and cats	Quarantine animal; treat only if animal develops symptoms.
Stray or sick dogs and cats	Submit animal’s head for testing. Delay treatment until test results are known unless clinical likelihood of rabies is high. If animal is unavailable, then complete full series of HRIG/RIG and HDCV.
Rodents, rabbits	Unlikely to be rabid (except woodchucks). Treat only if animal acted strangely and cannot be tested.

HDCV, Human diploid cell vaccine; HRIG/RIG, human rabies immunoglobulin. From Centers for Disease Control and Prevention. Human rabies prevention—United States, 1999. Recommendations of the Advisory Committee on Immunization Practices (ACIP). *MMWR Morb Mortal Wkly Rep.* 1999;44(RR-1):1–21.

caused by *Streptobacillus moniliformis* or *Spirillum minus*, is one such example. The American Academy of Pediatrics *Red Book* contains comprehensive, up-to-date descriptions of unusual diseases transmitted by various domestic and wild animals.

## ANTICIPATORY GUIDANCE

Although pets provide hours of delight and companionship for children, education about the responsible care of a pet is important. Preschool-aged children should not be left alone with a pet, and they should be advised never to tease animals, approach strange animals, or play with pets that are eating. Families who have children should be advised not to buy wild animals or dogs bred for aggressiveness. Finally, vaccinations for pets and routine visits to a veterinarian should be encouraged (see Chapter 42, Safety and Injury Prevention, for a more detailed discussion of animal safety rules for children). Families traveling with children should be on the alert for stray animals in foreign countries, given that animal control is often poor. If families are planning to spend an extended period in a country where rabies is endemic, then prophylactic rabies vaccine should be strongly considered.

### WHEN TO REFER

- Complex wounds that require surgical repair
- Bites to the face or hand that require plastic surgery
- Infected wounds not responding to initial treatment
- Children with human bites from an adult

### WHEN TO ADMIT

- Infected wounds requiring intravenous antibiotics
- Extensive facial wounds requiring skilled nursing care

## TOOLS FOR PRACTICE

### Engaging Patient and Family

## Chapter 216

# ANOREXIA NERVOSA, BULIMIA NERVOSA, AND OTHER EATING DISORDERS

Marcie Schneider, MD; Martin Fisher, MD

## INTRODUCTION

The eating disorders, a group of conditions that affect primarily adolescents and young adults, increased significantly in prevalence during the past several decades. From 1999 to 2006, there was an increase in hospitalizations for patients with eating disorders, especially those younger than 12 years. Marked by a combination of medical and psychological factors in their etiology and outcome, they include predominantly the well-known entities of anorexia and bulimia nervosa. Anorexia nervosa (AN) is viewed most simply as the purposeful loss of weight beyond a healthy state, whereas bulimia nervosa (BN) is marked by recurrent episodes of binge eating along with purging behaviors. The diagnosis and prevalence of these disorders are much debated, and many questions remain about their etiology and outcome. Nevertheless, the growing incidence and prevalence of eating disorders in adolescents and adults require that the primary care physician has some knowledge of the principles involved in the evaluation and treatment of both anorexia and bulimia nervosa.

## ETIOLOGY

Several factors most likely converge in the development of an eating disorder. The adolescent who is culturally primed, biologically at risk, and psychologically vulnerable may begin dieting or vomiting in response to a particular precipitant (often an insult by family or friends, exposure to another individual who has an eating disorder, or a stressful situation). The positive psychological feedback that initially accompanies a perceived improved appearance and the biochemical changes that occur in response to decreased nutrition may serve to perpetuate the behavior.

Genetic factors have been linked to anorexia nervosa and bulimia nervosa. There may be pubertal activation of these factors. Additionally, there is evidence of interplay between genetic and environmental factors. Leptin and endocrine abnormalities in the hypothalamic pituitary adrenal axis have been linked to eating disorders. Dieting itself is an important risk factor for developing an eating disorder. More recently the predilection of many in society to eat “healthy

diets” leads to dietary restrictions that cause weight loss and the onset of an eating disorder.

## DEFINITIONS

For more than 20 years, the diagnostic criteria for the eating disorders were based on the fourth edition (and fourth edition revised) of the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV and DSM-IV-TR)*. The publication of the Fifth Edition (*DSM-5*) in May 2013 has resulted in significant changes in the definition of the major eating disorders, which have, in turn, resulted in improved diagnostic accuracy. Whereas more than 50% of pediatric and adolescent patients with eating disorders were receiving diagnoses of “eating disorders not otherwise specified” (EDNOS) using the *DSM-IV* criteria, almost all children and adolescents with eating disorders are now receiving specific diagnoses using the new *DSM-5* criteria.

The 4 major eating disorders in the *DSM-5* are anorexia nervosa (AN), bulimia nervosa (BN), binge eating disorder (BED), and a newly described diagnosis referred to as avoidant/restrictive food intake disorder (ARFID).

Anorexia nervosa, per the *DSM-5*, is defined by the restriction of dietary intake, which results in a low body weight compared to what is expected in the context of the patient’s age, sex, pubertal stage, and physical health. Additionally, there is an intense fear of gaining weight and a distortion in body image. Patients are also categorized as having restricting or bingeing and purging subtypes of AN.

Bulimia nervosa, per the *DSM-5*, is defined by binge eating and participating in repeated behaviors to avoid weight gain (eg, vomiting; use of laxatives, diuretics, or diet pills; restricting food; and/or over-exercise) at least once a week over a three-month period of time. Patients with BN feel overly influenced by the appearance of their body.

Binge eating disorder, per the *DSM-5*, is defined by binge eating at least once a week for three months without any compensatory behaviors and marked distress about bingeing.

Avoidant/restrictive food intake disorder, per the *DSM-5*, is defined by a problem with eating that causes significant weight loss or lack of expected gain, a decline in social functioning, and possible dependence on nutritional supplements, all of which are not due to a medical cause or lack of available nutrition. Importantly, there is no body image distortion present, as is found in patients with AN.

Specific changes from *DSM-IV* to *DSM-5* in these diagnoses are as follows:

1. The requirements that an individual be at least 15% below ideal body weight (IBW) and have amenorrhea of at least 3 months have been eliminated from the diagnostic criteria for AN. In addition, a new category, called *atypical anorexia nervosa*, has been added, to account for those who have lost a lot of weight and have eating disorder thinking and behaviors, but who are not underweight. These changes have added significant flexibility to the diagnosis of AN, decreasing the need to categorize patients as having EDNOS, which was a frequent diagnosis using the *DSM-IV* criteria.

2. The diagnosis of BN is also more flexible, partly because the bingeing requirement was decreased from 2 times per week in *DSM-IV* to once per week in *DSM-5*, but more importantly because a new diagnosis of purging disorder has been added to *DSM-5*. This new diagnosis includes the many patients (especially adolescents) who purge but do not binge, who previously received a *DSM-IV* diagnosis of EDNOS.
3. Binge eating disorder has become an official diagnosis in *DSM-5*, after being a provisional diagnosis in *DSM-IV*. This diagnosis is made infrequently in children and adolescents, however, with most patients with BED being 18 years of age or older.
4. The new diagnosis of ARFID, on the other hand, very specifically applies to pediatric and adolescent patients. The patients who fit into the category of ARFID are those who have poor nutrition and/or weight loss or poor growth not resulting from a fear of weight gain. Subcategories of patients with the diagnosis of ARFID include those who have had a choking or vomiting episode that is making them afraid to eat, those with restricted diets since early childhood, and those who will not or cannot eat well because of gastrointestinal symptoms or anxiety.

## CLINICAL MANIFESTATIONS

### Incidence

#### Anorexia Nervosa

Conservatively, AN occurs in 0.5% to 1% of girls and young women and 0.2% of boys and young men. A bimodal peak of onset occurs during the adolescent years at 14.5 and 18 years of age. Increasingly, the onset of AN has been seen in both prepubertal children and adults. Mortality is higher than in any other psychiatric illness, up to 5% per decade after the onset of the eating disorder.

#### Bulimia Nervosa

Up to 15% of adolescents report binge eating, purging, or both. However, only 2% of female adolescents and 0.3% of male adolescents actually meet full diagnostic criteria for BN. The peak prevalence of lifetime BN is reported to be 2% to 4% among white Western girls and women aged 17 to 25 years, with a modal age of onset of 18 to 19 years. BN occurs in patients younger than age 14 years, but this situation is very rare.

### Risk Factors

#### Anorexia Nervosa

Serotonergic, dopaminergic, opioidergic, appetite regulatory, food intake regulatory, weight regulatory, and other genes have been explored as possibly causative in AN, but because samples are small and data are inconsistent, findings to date are inconclusive. Chromosomes 1, 2, 4, and 13 have possible links to AN. Low self-esteem, perfectionism, and obsessiveness are associated with AN. Additionally, a family history of eating disorders, family dieting, and a focus on weight in the family are all linked to the onset of AN. Interestingly, very preterm small-for-gestational-age infants have a higher risk for developing AN. Psychiatric illnesses can coexist with AN, including depression, anxiety, and obsessive-compulsive disorder.

### **Bulimia Nervosa**

Dieting has been documented as a risk factor for the development of BN. Chromosomes 10 and 14 have been linked to BN. As with AN, particular gene categories may be involved, but the studies are inconclusive. BN is associated with early menarche, early sexual experiences, and increasing age in girls and with very early or late puberty and early sexual experiences in boys. Personal and parental obesity are each risk factors for BN. Urbanization, not socioeconomic status, has been found to be a risk factor for BN, which occurs at a rate 5 times higher in large cities than in rural areas. Because it occurs in all ethnic and racial groups, being a member of an ethnic subculture does not apparently protect against the sociocultural factors that promote body dissatisfaction among teenage girls. Childhood sexual abuse has been reported to be a significant risk factor, especially when psychiatric comorbidity is present. Premorbid negative self-evaluation, parental alcoholism, low parental contact, and high parental expectations have each been associated with a higher risk for development of the disorder. In addition, BN is associated with impulsivity, stressful life events, high levels of family conflict, inadequate expression of emotions, lack of parental warmth and care, inappropriate parental control, and a family history of affective disorders or eating disorders. A family history of eating disorders increases the risk for having an eating disorder by 7- to 12-fold. A greater prevalence of eating disorders in monozygotic versus dizygotic twins is present, and 54% to 83% of the variance in BN can be accounted for by genetic factors. Twin studies have shown AN to be heritable in 33% to 84% of cases and BN heritable in 28% to 83%. Molecular genetic research on several genes, including the most recent study on estrogen-related receptor  $\alpha$  (ESRRA) and histone deacetylase 4 (HDAC4) mutations, provide a new and exciting area of study aimed at gaining an understanding of the genetics of these disorders.

### **DIFFERENTIAL DIAGNOSIS**

The differential diagnosis of the eating disorders includes possible medical causes of weight loss or vomiting and other psychiatric causes of poor appetite. Included in the differential diagnosis are malignancies and central nervous system tumors; gastrointestinal problems, including malabsorption, celiac disease, and inflammatory bowel disease; endocrinologic problems such as diabetes mellitus, hyperthyroidism, and hypopituitarism; chronic illnesses and chronic infections; and the superior mesenteric artery syndrome. The history, physical examination, and baseline laboratory tests should help rule out most of these diagnoses; further testing may be necessary if the weight loss or vomiting cannot be explained adequately. Magnetic resonance imaging (MRI) of the brain, gastrointestinal series, or other tests may be considered in some cases for patients who claim to be eating well or not vomiting on purpose. In some instances, a patient may show obvious pleasure in the weight loss or vomiting brought on by another disorder; however, this circumstance must not be confused with a positive diagnosis

of AN or BN. Psychiatric causes of weight loss can include depression, obsessive-compulsive disorder, and psychosis (especially schizophrenia). The patient who refuses to eat because of a desire to lose weight must be differentiated from the patient who cannot eat because of depression or the patient who will not eat because of delusional fears (eg, that the food is poisoned). Although patients may have concomitant depression or psychosis with AN or BN, separate criteria must be used to establish each entity. A full psychosocial history must be obtained as part of the initial evaluation to establish both the diagnosis and the psychosocial severity of the disorder. The patient's functioning in the family, in school, and among peers must be evaluated, and possible psychiatric symptoms such as sleep disorders, hallucinations, delusions, or obsessions should be elicited. Almost all patients with eating disorders exhibit psychosocial changes with the onset of the illness. These changes generally include fighting with the family, withdrawing from friends, and performing less optimally in school, although some patients paradoxically report improved school performance as they withdraw from friends and family. If additional psychiatric symptoms are found, the possibility of an additional diagnosis should be pursued.

### **EVALUATION**

Evaluation of the specific diagnostic criteria for eating disorders listed in the *DSM-5* serves to both elucidate the diagnosis and determine the severity of the illness. Distortion of body image, a hallmark in the diagnosis of AN, may be evaluated by exploring the patient's views of initial, current, and desired weight. Establishing the patient's eating and exercise patterns and use of vomiting or medications designed to promote weight loss (including diet pills, laxatives, diuretics, or ipecac) provides hints to both the diagnosis and the possibility of medical complications. Care must be taken to avoid being misled by the patient who is not completely forthright; the results of the physical examination and laboratory tests often suggest the true extent of the patient's disorder.

### **Anorexia Nervosa**

#### **History**

Initial evaluation of the patient with weight loss includes a determination of the diagnosis and its severity, an evaluation of other possible causes of weight loss and the effects of malnutrition, an analysis of the psychological context of the illness, and a decision about treatment. Relevant history includes patients' recollection of height, maximum weight, minimum weight, current weight, and desired weight. Additionally, evaluation for a distortion in body image, a history of bingeing or purging, and overexercising is necessary. On the review of systems, symptoms of malnutrition, including alopecia, cold hands and feet, dry skin, constipation, fatigue, and amenorrhea, may be present (Box 216-1). For girls, a full menstrual history should be obtained, including age at menarche, last normal menstrual period, usual length of menses, heaviness of flow, presence of dysmenorrhea, and regularity of menses.

### BOX 216-1 Physical Findings and Medical Complications of Anorexia Nervosa and Bulimia Nervosa

#### ANOREXIA NERVOSA

- Acrocyanosis
- Alopecia
- Dry skin
- Lanugo
- Ecchymosis
- Fatigue
- Hypothermia
- Muscle wasting
- Bloating
- Postprandial fullness
- Decreased subcutaneous fat
- Decreased deep-tendon reflexes
- Constipation
- Delayed gastric emptying
- Delayed gastric motility
- Orthostatic hypotension
- Bradycardia
- Mitral valve prolapse
- Pericardial effusion
- Electrocardiographic abnormalities, including prolonged QT interval
- Decreased left-ventricular mass and contractility
- Psychomotor retardation
- Growth delay
- Pubertal delay
- Amenorrhea or menstrual irregularity
- Osteopenia, osteoporosis
- Cortical atrophy on magnetic resonance imaging

- Electrolyte abnormalities from water loading or purging
- Hypercholesterolemia without hyperlipidemia
- Euthyroid sick syndrome
- Low luteinizing hormone, follicle-stimulating hormone, prolactin
- Elevated cortisol level
- Low insulin-like growth factor 1
- Low leptin

#### BULIMIA NERVOSA

- Hypertension or hypotension
- Electrolyte abnormalities, including hypokalemia, hypochloremia, elevated serum bicarbonate
- Dehydration
- Erosion of dental enamel
- Calluses on the dorsum of the hand
- Parotid enlargement
- Acute pancreatitis
- Acute gastric dilation or rupture
- Mallory-Weiss tears
- Gastric and esophageal irritation
- Gastric and esophageal bleeding
- Gastric esophageal reflux disease
- Barrett esophagus
- Aspiration pneumonia
- Diarrhea, constipation, steatorrhea
- Emetine cardiomyopathy
- Menstrual irregularity
- Polycystic ovarian syndrome
- Osteopenia, osteoporosis

#### Physical Examination

The first steps in the physical examination of the patient who is thought to have AN include measuring height, weight, and vital signs; plotting the height, weight, and body mass index (BMI) on the patient's growth curve; and calculation of the percentage below ideal body weight (IBW). The percentage below IBW, which may be calculated by comparing the patient's current weight with the average weight expected for height, age, and sex (as determined by standard pediatric growth charts), serves both as one of the diagnostic criteria and as a gross estimate of the degree of malnutrition. In general, body weight more than 25% below IBW represents severe malnutrition, 20% below IBW represents moderate malnutrition, and weight not yet 20% below IBW represents mild malnutrition. For example, a 16-year-old girl who is 5 feet 4 inches tall would be expected to have a body weight of 120 pounds, plus or minus 10%; she would be 20% below IBW at 96 pounds and 25% below IBW at 90 pounds. Pediatric growth charts ([www.cdc.gov/growthcharts](http://www.cdc.gov/growthcharts)) are needed especially

for premenarchal girls and growing boys to determine previous heights and weights to establish appropriate weight goals for achievement of expected adult height. Plotting height, weight, and BMI on the patient's growth curve gives perspective to the current weight and the current height. Vital signs provide further evidence of the degree of malnutrition because chronic malnutrition is accompanied by declines in blood pressure, pulse, and electrocardiographic voltage. Other cardiovascular changes can include sinus bradycardia, prolonged QTc, orthostatic hypotension, increased vagal tone, poor myocardial contractility, mitral valve prolapse, pericardial effusion, and decreased left-ventricular mass. To document orthostatic changes accurately, the patient's blood pressure and pulse should be checked in the sitting position, followed by standing for 2 minutes. An increase of 20 beats per minute in pulse, a decrease of 20 mm Hg in systolic blood pressure, or a decrease of 10 mm Hg in diastolic blood pressure is considered significant. Other physical findings associated with malnutrition include scaphoid abdomen,

muscle wasting, acrocyanosis, decreased subcutaneous fat, lanugo hair similar to that seen in newborns, ecchymoses, diminished reflexes, and dry skin.

### Laboratory Evaluation

Laboratory tests further elucidate the severity of the illness. Most patients who have anorexia nervosa have normal laboratory results initially, although all organ systems are probably affected by the malnutrition. The laboratory abnormalities found on routine testing are related generally to the individual's particular nutritional pattern. Thus, the patient who is chronically malnourished may have leukopenia, occasionally thrombocytopenia, and, in rare cases, severe anemia (being protected for some time from iron-deficiency anemia by the concomitant amenorrhea). The patient who restricts fluid intake may show evidence of dehydration (including an elevated sodium or blood urea nitrogen), whereas the patient who drinks excessive fluids to satisfy hunger or the physician's scale may show signs of hyponatremia and dilute urine. Conversely, the patient who vomits or uses laxatives may show evidence of hypokalemia, which is often severe in persons who use both methods of weight control. Nutrient values, including levels of zinc, calcium, magnesium, copper, vitamin B<sub>12</sub>, and folate, may all be altered in the malnourished patient, but are usually normal. Hormonal testing may produce evidence of dysfunction in endocrine systems. Development of a relative hypothyroidism caused by a combination of euthyroid sick syndrome and decreased production on a hypothalamic basis is believed to be an adaptive response to inadequate nutrition. Hypothyroidism is generally evident by low-normal levels of triiodothyronine, thyroxine, thyroid-stimulating hormone, or any combination. Amenorrhea, or menstrual irregularity, may develop and is accompanied by low levels of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Hypercortisolemia with loss of diurnal variation, low levels of insulin-like growth factor 1 (IGF-1) and leptin, increased ghrelin, and increased peptide YY are seen in patients with AN, although these tests need not be performed in most patients.

In general, the initial laboratory workup of patients with AN includes a complete blood cell count, evaluation of serum electrolytes, liver and thyroid function tests, and levels of LH, FSH, estradiol, and prolactin in patients who have amenorrhea. Obtaining a urinalysis for specific gravity and ketonuria is often helpful. An electrocardiogram (ECG) is performed for persons with bradycardia. This battery of tests is generally sufficient to provide a barometer of current status, a baseline to monitor further changes, and screening for other possible causes of weight loss. Data have demonstrated that patients who have eating disorders, especially those whose amenorrhea is prolonged because of malnutrition, show evidence of osteopenia on bone density studies. Initial studies have shown that this effect may not be preventable, even with calcium supplementation or hormonal replacement, or completely reversible, even after patients regain their normal weight. A threefold increase in the long-term risk for fracture development has been seen in patients with a history of AN. Studies are underway to

determine the possible causes of osteopenia, including hypoestrogenemia, hypercortisolemia, and decreased IGF-1. Bone density values in patients with AN are correlated with BMI, age at onset, and duration of illness. Bone densitometry, using dual-energy x-ray absorptiometry, has become a common test in the evaluation of patients who have eating disorders and amenorrhea of at least 6 to 12 months' duration. Evidence of abnormalities may be found on computed tomography and MRI of the brain, but these tests are generally reserved for evaluating other possible causes when the diagnosis is in question. MRI changes in the brain, including gray matter deficits and increased ventricular volume seem to be reversible with weight recovery. Additionally, delayed gastric emptying and decreased gastrointestinal motility can be seen in AN. Gastric emptying studies can be done to evaluate these abnormalities, if necessary.

### Bulimia Nervosa

#### History

Initial evaluation of a patient with BN includes determining the diagnosis and its severity and evaluating other causes of the symptoms. Relevant history includes frequency of bingeing; frequency of purging behaviors, including laxative, diuretic, diet pill, or ippecac use; and frequency of vomiting or exercising. History of maximum, minimum, and usual weight is also obtained. Similar to patients with AN, symptoms of malnutrition, including cold hands and feet, hair loss, and irregular menses, may be present. Symptoms related to purging, which include heartburn, hematemesis, constipation, and diarrhea, should be explored.

#### Physical Examination

Patients with BN may be underweight, overweight, or normal weight. Specific abnormalities on the physical examination are rarely found; therefore, more subtle changes in vital signs, the complete physical examination, and laboratory tests should be sought (see Box 216-1). Vital signs will vary depending on the substances used to control weight. For example, persons using diet pills may have tachycardia, hypertension, or both, whereas those using substances that cause dehydration, such as stimulant laxatives or diuretics, may have tachycardia, hypotension, or both. Vomiting can cause hypovolemia and, in turn, tachycardia and hypotension. For persons who exercise excessively, resting heart rates may show significant bradycardia. Thus, the initial physical examination generally begins with measurements of weight, height, blood pressure, and pulse. If dehydration needs to be ruled out, then measuring blood pressure for orthostatic changes as previously described is needed. Hands should be examined for Russell sign (ie, irritation on the dorsum of the joints of the fingers used to induce vomiting); teeth should be examined for erosion of enamel as a result of vomiting; and parotid enlargement from vomiting may also be seen.

#### Laboratory Evaluation

Blood tests include a complete blood cell count with differential, electrolytes, lipid studies, liver function

tests, and serum chemistries. Amylase levels and urinary pH may be elevated in some patients who have BN. The urinalysis may reveal an elevated specific gravity in dehydration, ketones in starvation, increased pH in the presence of vomiting, or any combination. A hormonal workup is performed if menstrual periods are problematic; these tests include thyroid function tests, as well as assessments of LH, FSH, estradiol, and prolactin (if amenorrheic). If potassium levels are abnormal or if a history of ipecac use exists, then an ECG should be performed. If patients are oligomenorrheic or amenorrheic, then a bone density assessment looking for osteopenia should be pursued.

### Binge Eating Disorder

The prevalence of BED among adults 18 years and older is 1.6% in females and 0.8% in males, and BED is equally prevalent across racial and ethnic groups. Between 1% and 2% of adolescents have BED. Most patients with BED are overweight, so obese populations have a higher prevalence of BED compared with nonobese populations. The mean age of onset of BED is 17.2 years. Binge eating predates dieting (14.3 and 15.0 years of age, respectively). Half of those with BED had the onset before the age of 18 years. Of those with the younger age of onset, weight problems, followed by bingeing, and then dieting started at a mean age of 12.2 years, 12.8 years, and 14.4 years, respectively. Because of the frequency of onset in the adolescent years, BED is important to recognize. Because patients with BED are not purging, there are fewer medical risks aside from those significantly related to obesity, which are beyond the scope of this chapter.

### Avoidant/Restrictive Food Intake Disorder

In studies reviewing patients with eating disorders who were classified under the new *DSM-5* criteria, 5% to 22% qualified for the diagnosis of ARFID. The limited study on this group of patients to date suggests that they are younger, more reliant on nutritional supplements, and may have fears of vomiting, choking, or the texture of food. Anxiety is more prevalent in the group of patients with ARFID than in those with other eating disorders. As much as this is a definition separate from AN because there is no body image distortion, the medical findings on physical and laboratory examinations and the medical ramifications are the same as with AN.

## TREATMENT

The patient who has an eating disorder may seek medical care in a variety of ways. Some patients visit their pediatrician or family physician because of concern about weight loss, vomiting, or abnormal eating attitudes noticed by family, friends, or school authorities; others visit a gynecologist because of the menstrual irregularities that characteristically accompany the disorder. Many patients are seen first by a psychiatrist, psychologist, or social worker; others may be seen for the first time in an emergency department because of dehydration or other medical complications. Some patients may be seen within weeks of the disorder's onset; others

avoid medical care for months or even years. Being brought in for their initial evaluation against their will is common for many patients, although some may seek help willingly. Many patients who have mild to moderate eating disorders, both AN and BN, avoid medical care altogether by hiding or denying their illness.

### Team Approach

The combination of medical and psychological interventions required in the treatment of eating disorders makes the task of being proficient in all aspects of care difficult for any single professional. No single individual can be responsible totally for any patient's care beyond the initial evaluation or for the most straightforward of cases. Rather, a team approach is most often used. The team may consist of a primary care physician; a psychiatrist, psychologist, or social worker; and a nutritionist, with the exact combination determined by local expertise, availability, and preference. Generally, each team member manages specific aspects of care, and team meetings and discussions are held frequently to prevent miscommunication that can sabotage the treatment.

### Medical and Nutritional Rehabilitation

Determination of the treatment setting as inpatient, outpatient, or in a day program is made by the evaluating provider. The malnutrition that accompanies AN is directly responsible for most, if not all, of the physical abnormalities noted in the disorder, as well as for some of the mental deterioration. Accordingly, medical and nutritional rehabilitation is crucial in the treatment of the patient who has AN. Restoration of body weight, generally to within 10% of IBW, with restoration of menses if amenorrheic, should be among the main goals of treatment. For many patients whose malnutrition is mild to moderate (15% to 25% below IBW), this task may be accomplished on an outpatient basis; patients who have moderate to severe malnutrition (more than 25% below IBW) can rarely accomplish the required weight gain without hospitalization. Medical treatment includes management of electrolyte abnormalities, cardiovascular issues, endocrine disorders, and other organ system dysfunction. These aspects of care are managed simultaneously with and are abetted by nutritional rehabilitation, which is generally achieved through oral feedings. Whether in the inpatient or outpatient setting, a daily intake of 3 substantial meals and 3 to 4 snacks is usually sufficient to bring about required weight gain and improvement of medical parameters. On inpatient units, meals are generally provided as part of a strict regimen, and snacks generally consist of high-calorie supplements, available as liquids or puddings in various brands and flavors. Care is taken to avoid overfeeding patients whose malnutrition is severe because a too-rapid weight gain has been associated with severe metabolic abnormalities (that is, the refeeding syndrome) in some patients. Slow refeeding and phosphorus supplementation are required in patients with severe malnutrition to prevent this syndrome, which may result in cardiac failure, hemolysis, coma, and death. For BN, the medical rehabilitation is focused on treating the patient's physical symptoms or

laboratory abnormalities and stopping or at least decreasing the patient's participation in risky behaviors, including bingeing, vomiting, and laxative and diet pill abuse, while the nutritional rehabilitation is focused on normalizing eating patterns and ensuring balanced nutrition.

### **Dietary Plan**

In the outpatient setting, an appropriate meal pattern may be developed based on the patient's and the family's prior eating habits or on a specific dietary plan offered by the physician or a nutritionist, or by the parents if they are in family-based treatment. The dietary plan should be specific to prevent ambiguities that can lead to family fighting; it should provide approximately 2,000 to 3,000 calories a day. Some of these calories may be supplied in the form of high-calorie supplements. The plan should be well balanced and include foods from each of the major food groups. Outpatient gains should be 1 to 2 pounds per week, whereas inpatient gains may be 2 to 4 pounds per week. Compliance with the dietary regimen may be evaluated by having the patient keep a diet diary; however, many patients do not always keep these records accurately and honestly. A similar dietary plan, without the high-calorie supplements, may be offered to healthy-weight patients who have BN because these patients generally require nutritional adjustment rather than nutritional rehabilitation. Caloric requirements for persons with BN will depend on the need for weight gain, loss, or maintenance. Because caloric restriction may often spark binge eating episodes, the implementation of a nonrestrictive, well-balanced diet is warranted. If hospitalization is necessary for uncontrolled binge or purge cycles, abnormal electrolytes, or unstable vital signs, then supervision after meals, locked bathrooms, and restricted access to food are often necessary.

### **Menses Restoration in Those With Amenorrhea**

Menses restoration generally requires an estradiol level of 30 to 50 mg/dL. Resumption and presence of menses have been linked to improved cognitive function in patients with AN. Researchers are exploring other treatments, such as recombinant human IGFs, dehydroepiandrosterone, bisphosphonates, testosterone, and a combination of recombinant human insulin-like growth factor (rhIGF1) and oral estrogen, in an effort to find ways to protect the bones of patients with eating disorders. Oral estrogen-progesterone combination pills are not effective in increasing bone density. Physiologic estrogen replacement in the form of a transdermal patch along with cyclic progesterone has been found to possibly increase the rate of bone accrual in adolescents with AN in one recent study. Still, regaining weight is the only definitive treatment to bring about the return of menses.

### **Treatment Settings**

#### **Inpatient and Residential Settings**

Patients are admitted to inpatient hospitals for the reasons previously outlined, which are either medically or psychiatrically emergent. They are put on

protocols to ensure weight gain and to guard against refeeding syndrome. Many units begin with food, moving to oral supplements or nasogastric feeds if meals are not consistently consumed. In fact, there is some evidence that using nasogastric tubes at the time of admission can increase the rate of weight gain.

After patients are stabilized, they are often transferred to residential programs, which have less medical monitoring and more psychological support. Various behavioral approaches may be used, including several phases of treatment, with patients moving from one phase to another based on achievement of progressively higher weight goals or improved behaviors or attitudes. Each phase incorporates additional privileges into the patient's daily activities (eg, food choices, food preparation, passes for outings with family).

### **Day Programs and Intensive Outpatient Programs**

After patients are ready to leave the residential setting, they are stepped down to a day program, which generally runs 5 days a week, providing 2 to 3 meals and snacks daily. Following this, it is ideal to step down again to an intensive outpatient program (IOP), which generally runs 3 hours per day, 3 days a week, providing a meal and a group. In both settings, patients still live at home, and with the IOPs, patients can attend school. Often, IOP and day programs are used as a step up from a general outpatient setting, in an effort to avoid the next higher level of care.

### **Outpatient Settings**

This least intensive option often includes medical monitoring, nutritional support, psychiatric treatment, and therapy, which may include individual, family, and/or group therapy.

### **Therapy Options**

Individual therapy, cognitive behavioral therapy (CBT), dialectical behavioral therapy (DBT), and family-based treatment (FBT) are the most commonly used modalities for patients with eating disorders. Individual therapy is varied and difficult to study for this reason.

Cognitive behavioral therapy was formulated by Fairburn in 1981. Use of CBT for eating disorders is aimed at decreasing nutritional restriction, normalizing eating, developing skills for coping with situations that trigger binge eating or purging (or both), and changing perceptions and overconcern with body weight and shape. CBT is the treatment of choice in adults with BN and BED. Both CBT and FBT have also been studied in adolescents with BN and found to be effective.

Family-based treatment was developed at the Maudsley Hospital in England and is often referred to as the *Maudsley approach*. In this method, there is no blame placed on parents or the patient. Rather, there is an understanding that the parents need to manage the patient's eating because the patient has not been able to do that and that the patient's health is in jeopardy. Parents are, therefore, empowered to refeed their child. The entire family is involved in the treatment. There are 3 phases—refeeding by caregivers, transferring the eating responsibility back to the

patient, and working on relapse prevention. The therapist needs to be trained in this method. Using this method, 50% to 60% of patients are in remission by the end of the first year, 25% to 35% practically recover, and 15% are resistant. This is in comparison to those who receive more traditional treatment, of which less than half recover within 2 to 5 years, one-third have partial recovery, and 20% are resistant. Because of these statistics, FBT has become a first-line treatment in many settings when there is a trained therapist available.

### Psychopharmacologic Therapy

The use of medication to treat eating disorders has a long history of decidedly mixed results. Numerous medications have been tried, from thyroid hormone and insulin in the 1940s and 1950s to phenytoin and hydroxyzine in the 1960s and 1970s, as attempts were made to improve appetite, increase weight gain, and reverse physiologic abnormalities. More recently, pharmacologic treatment of the eating disorders has concentrated on psychoactive medications, especially the selective serotonin reuptake inhibitor (SSRI) antidepressants. Two specific lines of reasoning have guided the use of these medications. In patients who are diagnosed as having an eating disorder along with, or as part of, another psychiatric diagnosis, medication for the associated diagnosis is offered with the expectation that the eating disorder will improve as other psychiatric symptoms are relieved. Alternately, more recent evidence has demonstrated that use of these medications diminishes the urge to binge and purge in patients who have BN and helps treat obsessive-compulsive symptoms in patients with either AN or BN. Only physicians who are familiar with the use of psychopharmacologic agents should prescribe these medications as part of the treatment, given the recent concerns about the potential for SSRI medications to increase the risk for suicide in a minority of children and adolescents treated for depression. The SSRI medications have not been shown to be effective in promoting weight gain in AN or treating symptoms of depression or obsessive-compulsive disorder when body weight is low; some questions remain about whether they may be effective in preventing relapse in patients initially treated successfully for AN. Atypical antipsychotic agents at low doses can improve weight gain and treat symptoms of depression and obsessional thoughts in patients with severe eating disorders, including both AN and BN. Again, only physicians who are familiar with the use of psychopharmacologic agents should prescribe these medications as part of the treatment.

Various types of antidepressant medications have been studied for the treatment of BN, including tricyclics, monoamine oxidase inhibitors, and SSRIs. All of these agents seem to be roughly equivalent in decreasing bulimic behaviors at the end of short-term treatment; with any of these medications: approximately 30% of patients are abstinent, and 70% have decreased bulimic behaviors. Fluoxetine has been the most intensively studied medication: a dose of 60 mg per day has been found to yield the best treatment outcome for

decreasing bulimic symptoms, relieving symptoms of depression and anxiety, and decreasing concerns with shape, weight, and desire to restrict food intake. Topiramate has been effective in decreasing binge eating if the SSRIs are not of help. Other drugs, including anticonvulsants, serotonergic agents, and lithium, have also been studied, with modest (anticonvulsants) or no significant (serotonergic agents or lithium) changes in symptoms. Use of CBT, followed by the introduction of medication if necessary, has been suggested as a logical treatment approach in the treatment of BN.

### OUTCOME AND PROGNOSIS

Eating disorders must be viewed as a chronic illness, similar to other medical or psychiatric chronic illnesses. A wide range of outcomes can be expected. Adolescents who have severe AN have a protracted disease course, yet recovery estimates 10 to 15 years later vary from 24% to 76%. Although many different approaches are used to evaluate outcome, at least an estimated 50% of patients do well in the long term, 30% show varying degrees of improvement, and 20% do poorly despite adequate treatment. Patients who are younger, as well as those whose forms of the disease are milder, appear to have a better prognosis than these general numbers indicate. Follow-up of patients with BN has recently been reviewed and has improved in studies done after 2004 compared with those done before 2004. Approximately 70% recover, 20% experience relapse, and 10% continue to meet the full criteria for BN 5 years after diagnosis. Numerous personal, family, and treatment factors may predict the outcome of an eating disorder; none of these may be predictive for an individual patient. For instance, a poorer outcome in AN has been associated with factors such as older age, vomiting, and premorbid personality problems, yet any particular patient who has this constellation of findings may do well with treatment. Furthermore, no specific treatment has been shown by controlled studies to be more effective than others, in general or for any particular type of patient.

### PREVENTION

Although a focus on both primary and secondary prevention has increased of late, the best strategies for the prevention of eating disorders remain unclear. There is increasing evidence that eating disorders and obesity may be related, with dieting, weight-related teasing, and body dissatisfaction as risk factors; therefore, using an integrated approach to prevention is sensible. To date, several programs geared toward both teenage boys and girls, primarily in school settings, have been implemented. These programs generally provide factual information and are aimed at maintaining a healthy body image, healthy eating, and promoting self-esteem without relation to weight, and they appear to succeed in terms of increasing awareness of and knowledge about eating disorders. However, whether these programs prevent or actually promote eating-disordered behaviors is debatable. The concept of preventing eating disorders through more generic programs focused on building self-esteem is currently being explored. In keeping with this effort, the concept

of a comprehensive school-based approach has been advocated. This approach would include classroom interventions, staff training throughout the school, informal discussions between staff and students, integration of material about eating issues into the curriculum, more intensive work with persons at high risk, changes within the school with respect to cafeteria food and physical education, and referrals and outreach, both within the school and to the community. A recent meta-analysis of prevention studies found that interactive, multiple sessions targeted at those at risk and older than 15 years were the most likely to succeed. Early case detection remains the most effective preventive measure currently available. For most patients, the earlier an eating disorder is treated, the easier the treatment will be and the less entrenched the disease becomes. Therefore, families, friends, school personnel, and health professionals must be vigilant for the signs and symptoms of an eating disorder so that early treatment can be initiated.

### WHEN TO REFER

- If the patient is medically stable, refer to a therapist. Also refer to a dietitian to reinforce the primary care physician's nutritional recommendations or to set a nutritional plan with the patient if the primary care provider does not have the time or expertise.
- Refer to a psychotherapist if the patient is open to therapy.
- Refer to a psychotherapist if the patient is unable to attain goals set by the physician, even if the patient is resistant.
- Refer for psychopharmacologic evaluation if both the physician and the therapist believe that the patient might benefit from medication (if the patient is bingeing and open to medication or if obsessive-compulsive symptoms are interfering with treatment).
- Refer to an adolescent medicine specialist if the primary care physician is not comfortable with treating the patient or does not have the time to do so, or if the patient does not adhere to the physician's treatment plan.

### WHEN TO ADMIT

Anorexia nervosa:

- Less than 75% ideal body weight or ongoing weight loss despite intensive management
- Refusal to eat
- Body fat <10 %
- Heart rate <45 beats/min daytime; <40 beats/min nighttime
- Systolic pressure <90 mm Hg
- Orthostatic changes in pulse (>20 beats/min) or blood pressure (>10 mm Hg)
- Temperature <96°F
- Arrhythmia
- Failure to respond to outpatient treatment

Bulimia nervosa:

- Syncope
- Serum potassium concentration,  $\leq 3.2$  mmol/L
- Serum chloride concentration <88 mmol/L
- Esophageal tears
- Cardiac arrhythmias including prolonged QTc
- Hypothermia
- Suicide risk
- Intractable vomiting
- Hematemesis
- Failure to respond to outpatient treatment

## Chapter 217

# APPARENT LIFE-THREATENING EVENTS

Keyvan Rafei, MD; Carol J. Blaisdell, MD

Apparent life-threatening events (ALTEs) in infants younger than 12 months are common and often present challenging diagnostic dilemmas for first responders and pediatricians. Although most patient evaluations usually take place in a hospital, primary care physicians often are asked to contribute to various stages of the management of these children, from initial evaluation of the infant to decisions about long-term monitoring. The reported incidence of infants experiencing ALTEs ranges from 0.6% to 0.8%, although there is marked variation (0.05%–6%) depending on the affected infant's underlying risk factors. The management of a child with an ALTE requires an understanding of the constellation of symptoms exhibited by the infant, the broad range of potential underlying etiologies and contributing factors, and the appropriate management strategies.

In a 1986 National Institutes of Health Consensus Report on Infantile Apnea and Home Monitoring, an ALTE was defined as “an episode that is frightening to the observer and is characterized by some combination of apnea, color change, marked change in muscle tone, choking, or gagging” in which, “in some cases, the observer fears that the infant has died.” This definition was intended to replace the term *aborted crib death* or *near-miss sudden infant death syndrome (SIDS)*, which inappropriately implied an association between ALTEs and SIDS. An ALTE is not a diagnosis, but rather a reflection of a symptom constellation (“chief complaint”) that requires evaluation to determine an etiology that will guide both risk assessment and subsequent therapeutic response.

Infants with ALTEs are a heterogeneous group with varying ages and diverse pathophysiology as to the cause of the events. The clinical challenge is that most ALTEs are benign, yet it is important to identify any infant who presents with an ALTE that is a manifestation of a serious underlying illness, such as sepsis, seizures, or child maltreatment. A review of the infant's history and physical examination is important to identify the infant at risk for a future adverse event or serious underlying condition, the scope of diagnostic testing needed, and whether hospitalization is required.

Although not the primary focus of this chapter, it is important to define apnea. Apnea is typically classified into 3 categories based on the presence or absence of upper airway obstruction: central, obstructive, and mixed. Central apnea (CA) is characterized by a total cessation of inspiratory efforts with no evidence of obstruction. An infant with obstructive apnea tries to breathe against an obstructed upper airway, resulting in chest wall motion without airflow throughout the apneic episode. Mixed apnea consists of obstructed respiratory efforts, usually following central pauses. Upper airway obstruction occurs primarily in the pharynx, although it also may occur at the larynx or involve both the pharynx and the larynx.

To create a uniform framework and help pediatricians apply consistent definitions to concepts related to infant apnea, the NIH report provided a series of descriptors for the commonly used terms to describe infant apnea and respiratory patterns exhibited by infants. These definitions are listed in Table 217-1. Most notably, pathologic apnea was defined as “a respiratory pause that is prolonged, lasting 20 seconds or longer, or is associated with cyanosis, pallor, hypotonia or bradycardia.” In contrast, periodic breathing, which is commonly noted in young infants, is “a breathing pattern in which there are 3 or more respiratory pauses of greater than 3 seconds' duration with less than 20 seconds of respiration between pauses.”

**Table 217-1** Definitions of Breathing Patterns and Concepts Related to Apparent Life-Threatening Events (ALTEs)

CONCEPT	DEFINITION
Periodic breathing	A breathing pattern in which there are 3 or more respiratory pauses > than 3 seconds' duration with <20 seconds of respiration between pauses. Periodic breathing can be a normal event.
Apnea	Cessation of respiratory air flow. The respiratory pause may be central or diaphragmatic (ie, no respiratory effort), obstructive (usually because of upper airway obstruction), or mixed. Short (15 seconds), central apnea can be normal at all ages.
Pathologic apnea	Respiratory pause that is prolonged (20 seconds) or associated with cyanosis, pallor, hypotonia, or bradycardia
Apnea of infancy	Unexplained episode of pathologic apnea with onset at >37 weeks' gestational age in infants for whom no specific cause of ALTE can be identified
Apnea of prematurity	Periodic breathing with pathologic (symptomatic) apnea in a premature infant. Apnea of prematurity usually ceases by 37 to 38 weeks' postmenstrual gestation, but occasionally persists to 1 month past term (43–45 weeks' postmenstrual age)
Sudden infant death syndrome	Sudden death of any infant or young child that is unexplained by history and by postmortem examination (Note that death scene recreation where feasible is now an additional important factor to eliminate accidental suffocation as the cause)

From National Institutes of Health. Infantile apnea and home monitoring. *Natl Inst Health Consens Dev Conf Consens Statement*. 1986;6:1–10.

Pauses in breathing without any physiologic consequences also occur in premature infants and term newborns. Review of a detailed history and physical examination help the pediatrician separate pathologic from nonpathologic witnessed events.

More recently, in 2007, the American Academy of Sleep Medicine (AASM) defined CA in children as, “cessation of breathing during sleep without any breathing effort for a duration of 20 seconds or longer, or lasting at least 2 breaths’ duration with 3% oxygen desaturation or arousal.” The AASM further noted that, “In infants, the CA is at least 2 breaths in duration and is associated with a decrease in heart rate to less than 50 beats per minute for at least 5 seconds, or less than 60 beats per minute for 15 seconds. Periodic breathing is a form of CA that has been described as greater than 3 episodes of CA lasting 3 seconds separated by no more than 20 seconds of normal breathing.” Brief CAs following body movements and periodic breathing are common in healthy infants during the first months of life; the duration and frequency improves with age. These “physiologic” CAs lasting longer than 15 seconds reflect developmental immaturity and rarely persist after 3 months of age. Most apneas occur during rapid eye movement (REM) sleep or as the infant is transitioning between sleep states. See Chapter 337, Sudden Unexpected Infant Death for a more detailed discussion about SIDS; and Chapter 100, Respiratory Distress and Breathing Disorders in the Newborn and Chapter 112, Continuing Care of the Infant After Transfer From Neonatal Intensive Care for further information.

The understanding of the frequency, duration, and significance of episodes of apnea and periodic breathing in young infants has been enhanced by the seminal Collaborative Home Infant Monitoring Evaluation (CHIME) study that characterized the breathing patterns of 1,100 infants during sleep. The group of infants studied included healthy term infants, siblings of infants with a family history of SIDS, healthy preterm infants, and term and preterm infants with ALTE. Study findings demonstrated that in otherwise healthy young infants, apnea of 20 seconds’ duration not associated with bradycardia is common. Investigators also noted that extreme events, described as apneas longer than 30 seconds associated with bradycardia, occur more commonly in preterm infants and typically reduce in frequency approximately 1 month after reaching term gestation (after 43 weeks’ postmenstrual age). Developmental immaturity increases the risk for central and obstructive apneas and periodic breathing in preterm infants, particularly in infants born at less than 26 weeks’ gestation. Bronchopulmonary dysplasia is an additional medical comorbidity that contributes to a longer duration of apnea and bradycardia in extremely preterm infants.

## PREVALENCE

The exact frequency and prevalence of ALTEs are unknown because of difficulties in classifying the subjective and heterogeneous nature of presenting symptoms and discharge diagnosis. The reported incidence of ALTEs in infants varies widely, with estimates between 0.46 and 10 per 1,000 live births, accounting

for 0.8% to 1% of all emergency department (ED) visits of patients younger than 1 year and 2% of pediatric hospitalizations. Recurrence rates for ALTEs vary from 0% to 24%. A cause for the ALTE is identified in approximately half of the affected infants. The history may reveal that the infant has feeding difficulties, including feeding with cough, lack of coordination, or rapid feeding. Risk factors for ALTEs include second-hand smoke exposure, preterm birth, exposure to pertussis, respiratory syncytial virus, or recent general anesthesia. Premature infants are especially susceptible to ALTEs, with causes such as aspiration with feedings, anemia, hypoglycemia, posthemorrhagic hydrocephalus, cardiac arrhythmias, respiratory syncytial virus, bordetella pertussis, sepsis, gastroesophageal or laryngeal esophageal reflux disease with or without aspiration, and seizures. Infants with an ALTE are more commonly younger than 10 weeks, with a median age of presentation ranging between 7 and 8 weeks of age; sex distribution has been reported to reveal a male gender predominance. Approximately one-third of infants with an ALTE had a history of prematurity, and 19% had a history of a previous ALTE. The morbidity and mortality resulting from an ALTE vary by the underlying diagnosis; the mortality of infants with apnea of infancy ranges between 0% and 6%.

## APPARENT LIFE-THREATENING EVENT AND SUDDEN INFANT DEATH SYNDROME

Strong epidemiologic evidence suggests that ALTEs and SIDS are not related. The average age of patients with an ALTE is 1 to 3 months younger than that of infants who die of SIDS, and ALTE episodes are generally reported by parents and caregivers to occur during the day with the infant in supine position. Moreover, while SIDS mortality rates markedly decreased between 1986 and 1994, the incidence for ALTEs has not changed significantly. Despite the lack of an epidemiologic association between SIDS and ALTEs, it is important to note that a very small minority of ALTEs do go on to have SIDS and that a small minority of SIDS deaths had a preceding ALTE. Franco and colleagues identified in a group of infants who experienced an ALTE and impaired arousal response from sleep with fewer spontaneous arousals during non-REM sleep at 2 to 3 and 5 to 6 months of age. In addition, infants who experienced an ALTE had less total sleep time, less sleep efficiency, less REM sleep, more awake time, and more CAs between 2 and 3 months of age. Maternal smoking further impaired the infants’ arousal responses and sleep architecture, and increased obstructive episodes throughout the study period (2–9 months of age).

## SUDDEN UNEXPECTED POSTNATAL COLLAPSE

Sudden unexpected postnatal collapse (SUPC) is a rare but well-described event that includes both severe ALTE and sudden infant death occurring during the

first week of life in infants where the postnatal adaptation seems normal. The estimated incidence of SUPC in a presumably healthy infant after birth differs widely, ranging from 2.6 cases to 133 cases per 100,000. Reported instances of SUPC typically exclude infants with known risks for ALTE and SIDS, infants born at fewer than 35 weeks' gestation or with diagnosed congenital malformations, and babies who experience perinatal asphyxia. When a defined time for the SUPC event is described, approximately one-third of reported events occur during the first 2 hours, between 2 and 24 hours, and between 1 and 7 days after birth, respectively. Most reported events that occur within 2 hours of birth have been during skin-to-skin contact and the first breastfeeding attempt. The transition from fetal to extrauterine life could make the newborn more vulnerable during the first hours of life, because the initial surge of adenosine, prostaglandins, and catecholamines during and after birth is followed by a period of diminished responsiveness to external stimuli and increased vagal tone. Prone positioning of the infant placed in skin-to-skin care, unsupervised breastfeeding during the first 2 hours, primiparous mother, and parents left alone with the baby during first hours after birth as well as distractions, such as smartphone use, have been identified as contributing factors. Extensive use of smart phones, messaging, and social networking after delivery are of particular concern. Maternal fatigue and sedation following an exhausting labor has been speculated to be an additional contributing factor. Infants born late preterm and early term (37–38 weeks' gestation) comprise an important risk group. Mothers may fail to recognize their infant's deterioration because of inexperience and a lack of awareness of the signs that an infant is having difficulty. Signs such as a change in the infant's color or respiratory effort may also be more difficult to observe if maternal mobility is impaired because of pain, postoperative status, or spinal anesthesia.

Reported survival rates vary from 50% to 80%. Among survivors, half have neurologic sequelae. Among infants who die and undergo postmortem examination, underlying congenital anomalies and conditions have been described, including antenatal brain injury, infection, metabolic defects, congenital central hypoventilation syndrome, and congenital adrenal hypoplasia, as well as cardiac abnormalities such as structural anomalies, cardiomyopathy, infarction, and conduction abnormalities. In those infants dying unexpectedly in the first week of life, almost 60% of deaths are explained following postmortem examination. Improved information, active surveillance, and rapid hypothermia treatment in severe cases are recommended. All infants who suffer a sudden and unexpected cardiorespiratory collapse within the first week of life should undergo comprehensive investigation to determine the underlying cause. If the infant dies, a complete postmortem examination should be performed and should include metabolic, mitochondrial disorder, and genetic testing. This should be followed by a multidisciplinary investigation and case review that explores the family, obstetric, pregnancy, delivery, and postnatal history, including the health of the

infant until collapse, postnatal transition and feeding, circumstances surrounding collapse, and resuscitation details.

## DIFFERENTIAL DIAGNOSIS

Because an ALTE describes a subjective report of a clinical syndrome rather than a specific diagnosis, a variety of different disorders can lead to an episode. The most common types of problems associated with an ALTE are gastrointestinal, neurologic, respiratory, cardiovascular, metabolic, or endocrine in nature. The most common, specific diagnoses associated with ALTEs include gastroesophageal reflux (31%), seizures (11%), and lower respiratory tract infections (8%), although many different diagnoses have been recorded. Up to 50% of cases of ALTEs remain unexplained and are considered idiopathic.

Although gastroesophageal reflux (GER) is the diagnosis most often associated with an ALTE, its precise role in these cases is debated. A relationship between apnea and GER disease (GERD) has been posited, but a definite causal relationship has not been demonstrated. Hasenstab and Jadcherla studied a group of infants following ALTE episodes and assessed tidal ventilation, respiratory function, esophageal motility, and frequency of spontaneous respiratory events (SREs, defined as an apneic event lasting longer than 2 seconds with at least 2 missed breaths). SREs, common in otherwise healthy infants, occurred more often in ALTE infants, suggesting exaggerated respiratory inhibition during pharyngeal swallowing events. The significance of this presumed central respiratory discoordination and brainstem dysregulation of aerodigestion has not been fully delineated. Further research in this area is warranted, because treatment with H-2 blocker and proton pump inhibitor medications often prescribed to infants with histories of reflux and ALTE may not be efficacious.

Neurologic and respiratory disorders are the second and third most commonly associated diagnoses in patients with an ALTE. The most common specific diagnoses are seizures in the former category, and pertussis and respiratory syncytial virus infection in the latter. Other important but less common diagnoses in infants with an ALTE include urinary tract infections (UTIs), inborn errors of metabolism, cardiac arrhythmias, brain tumors, persistent ductus arteriosus, and opioid-related apnea.

Child abuse (nonaccidental trauma and suffocation) and factitious illness (caregiver-fabricated illness) may account for up to 11% of unexplained ALTEs. (Box 217-1). All pediatric providers should be aware of the potential relationship, be trained to recognize the historical features and physical examination findings, and have a systematic approach to screen all ALTE patients for abuse.

## EVALUATION

Most patients will be discharged from the ED or hospital without a specific diagnosis or with a self-limited condition not requiring treatment. However, a minority may have one of a vast array of occult disorders that can lead to significant morbidity or mortality if not identified. No single accepted standard exists for

**BOX 217-1 Signs of Intentional Suffocation**

When a death occurs in an infant with a prior history of apparent life-threatening event (ALTE), the following circumstances should indicate the possibility of intentional suffocation:

- Previous recurrent cyanosis, apnea, or ALTE while in the care of the same person
- Age at death older than 6 months
- Previous unexpected or unexplained deaths of 1 or more siblings
- Simultaneous or nearly simultaneous death of twins
- Previous death of infants under the care of the same unrelated person
- Discovery of blood on the infant's nose or mouth in association with ALTEs

Adapted from Hymel K; American Academy of Pediatrics Committee on Child Abuse and Neglect, and National Association of Medical Examiners. Distinguishing sudden infant death syndrome from child abuse fatalities. *Pediatrics*. 2006;118(1):421–427.

evaluating these events, but a stepwise approach beginning with a detailed history and physical examination is most prudent. A thorough clinical assessment is more likely than an array of diagnostic studies to lead to a diagnosis of the underlying problem. The selection of any diagnostic studies and the extent and duration of observation should be based on the findings of the clinical assessment and not on an undirected battery of tests.

**History**

Seeking a detailed history and description of the infant at the time of the ALTE is particularly important because most infants appear normal by the time of the evaluation.

The most important item of the history is to determine, if possible, whether an “event” actually occurred. If a reliable observer reports what seems to be a frightening event, the baby should be hospitalized to determine whether a cause for the event can be found. If the observer is unreliable, and the history is equivocal, the baby might be discharged from the ED. If the history is equivocal, the best choice may be to hospitalize and evaluate, especially in a community hospital where a pediatrician might not be available in the ED. Consistency of the described event should be evaluated because fabricated events may suggest child abuse. Important historical questions to address are listed in Box 217-2. The case in Box 217-3 provides an example of the type of young infant who might present to a pediatrician or an ED following a 911 call. Of note in this infant's history are risk factors related to the infant's preterm birth at 36 weeks' gestation, feeding difficulties, and history of recurrent emesis and exposure to secondhand smoke. In addition, the fact that the infant experienced a second episode during the transport to the hospital places the infant at greater risk and should prompt hospitalization and evaluation even if the infant seems well at the time of presentation to the ED.

A complete history should include a review of the patient's medical and family history, a description of the patient's living conditions, descriptions of events immediately before and during the ALTE, and prior history or family history of SIDS or ALTEs. All patients should be screened for risk factors for child abuse. The case in Box 217-4 illustrates the similarities in presentation between an ALTE and an occult brain injury following child abuse. This reinforces the importance of a thorough history and comprehensive evaluation when an infant experiences repeated or atypical events.

**Physical Examination**

Although most infants with an ALTE are found to be normal at the time of the initial evaluation, a detailed physical examination is essential to uncover any clues to the underlying cause. The pediatrician should pay particular attention to neurologic, respiratory, and cardiac abnormalities that may account for the infant's symptoms, noting any evidence for physiologic compromise (eg, mental status changes, cyanosis, apnea). Physical examination features for child abuse, such as unexplained bruising, bleeding, or petechiae of the face, should be noted. Documentation of physical findings of trauma should be well described in the chart and should include photographs labeled with the child's name and birthdate.

**Laboratory Evaluation**

No minimal standard set of diagnostic studies to evaluate infants with an ALTE has been developed. Although a detailed history of the event and the physical examination of the infant often yield a suspected cause for the ALTE, laboratory testing may be a useful adjunct to confirm the diagnosis. In infants younger than 12 months, the basis of the diagnosis can be found in 21% of patients by only history and physical examination. With no additional information gained from laboratory testing, the yield of diagnostic testing can be low (only 2.5%). Therefore, using the findings of the history and physical examination is important to direct appropriate diagnostic testing.

A greater challenge is presented by infants without suggestive findings at the initial history and physical examination. When selecting diagnostic studies for this group, it is important to remember that the yield of most studies is low, and even if a positive result is found, the question of a causal relationship still remains.

In evaluating an infant with an ALTE, the focus must be first on identifying emergent and life-threatening causes, and then on extending the evaluation to additional studies if no answers are found. Box 217-5 lists the evaluations that may be considered. These studies may not be available in all hospitals, and a pediatric specialist may need to be consulted to interpret the results of the tests.

When evaluating the infant with an ALTE, there is an associated diagnosis of GERD more than 50% of the time. However, this diagnosis likely includes common choking episodes following emesis or reflux of stomach contents. Such an event is most often a self-limited, mixed obstructive event. Although further

**BOX 217-2 Essential Elements in the History of Apparent Life-Threatening Events (ALTEs)****PERSONAL AND FAMILY HISTORY**

- Perinatal history
  - Full-term or preterm birth
  - Pregnancy or perinatal complications
- Medical and surgical history
  - Previous evaluations and treatments
  - Prior hospitalizations
  - Medications
- Feeding habits
  - Breastfeeding or bottle feeding
  - Usual amount and frequency of feedings
  - Timing of last feeding relative to the event
  - Feeding difficulties—choking, coughing, arching, grimacing, emesis/reflux episodes
  - Usual behavior and temperament
- Breathing and sleep history
  - Sleep patterns
  - Breathing irregularities, respiratory pauses or shallow breathing
  - Episodes of cyanosis, pallor
- Family history
  - Siblings with ALTE, sudden infant death syndrome, or early death
  - Family history of genetic, metabolic, cardiac, or neurologic problems
- Parental or caretaker history
  - Smoking or drinking habits
  - Recent medical problems and treatments

**DAILY LIFE CONDITIONS**

- Usual sleep conditions
  - Sleep position when placed down for sleep and when found
  - Sleep location
  - Sleeping attire
  - Bedding materials
- Other conditions
  - Clothing, accessories (necklace, bracelet)
  - Room temperature, overbundling
  - Use of pacifiers

**EVENTS IMMEDIATELY PRECEDING THE ALTE**

- Recent fever or illness
- Medications of the infant and others in the home

- Immunizations
- Sleep deprivation
- Change in daily life routine

**DESCRIPTION OF THE ALTE**

- Place and time
  - Exact place in which the ALTE occurred (eg, child's bed, parent's bed, parent's arms, bathroom, sofa, car)
  - Time of event
  - Time since last feeding
  - Estimated time to recover from the ALTE
  - Estimated duration of event
- Witnesses and interventions
  - Who discovered or witnessed the ALTE
  - Reason that led to the discovery of the ALTE (noise, unusual cry)
  - Any interventions performed (gentle stimulation, shaking, cardiopulmonary resuscitation)
  - Child's response to the intervention
- Description of infant during ALTE
  - State of infant when event began—asleep or awake
  - If asleep:
    - Child's body position
    - Type of bedding
    - Face covered or free
  - If awake:
    - Was the child being fed, being handled, crying, being bathed?
  - Child's appearance when found:
    - Consciousness
    - Muscle tone
    - Color
    - Respiratory effort
    - Choking
    - Gasping
    - Emesis
    - Sweating
    - Limb or eye movements
    - Pupil size
    - Skin or rectal temperature

Adapted with permission from Kahn A, European Society for the Study and Prevention of Infant Death. Recommended clinical evaluation of infants with an apparent life-threatening event. Consensus document of the European Society for the Study and Prevention of Infant Death, 2003. *Eur J Pediatr*. 2004;163(2):108–115.

workup or treatment may not be needed, infants with apparent symptomatic reflux may benefit from a trial of therapy with medication. Infants diagnosed with GERD are nearly 2 times more likely to have recurrent ALTE, and treatment with antireflux medications may lower this risk. Further evaluation may be indicated in less common events of “silent” reflux followed by CA

or aspiration requiring intervention. The upper gastrointestinal (UGI) series is not recommended to diagnose GERD, because GER is present in most infants. In rare circumstances, a UGI series may be used to identify intestinal obstruction (eg, volvulus, gastric outlet obstruction) or congenital esophageal abnormalities (eg, tracheoesophageal fistula, vascular rings)

**BOX 217-3 Case Report 1**

A 2.5-month-old infant was transferred to the local hospital ED after presenting to the primary care physician with a history of a frightening episode of cyanosis and hypotonia witnessed by the mother approximately 90 minutes after feeding. The infant responded to stimulation by the mother and at present is alert, well seeming, and active. Vital signs in the doctor's office were: HR 110, RR 30; T 99.1°F [37.3°C], SpO<sub>2</sub> 98%. During the ambulance ride to the hospital, the infant had a similar episode, becoming limp and pale with shallow, irregular respirations. Again, the infant responded to stimulation and on arrival at the hospital was alert and well seeming once again. Review of the infant's

medical history is notable for birth at 36 weeks' gestation with a newborn nursery stay of 6 days because of jaundice and feeding difficulties. The infant's birth weight was 2,850 g the maternal medical and pregnancy histories were unremarkable except for maternal gestational diabetes and maternal smoking before realizing she was pregnant. The mother disclosed that because of the stress of the baby needing special care in the hospital she had resumed smoking, although she was trying to limit her tobacco use and not smoke in the home. The infant is breast and formula feeding and is reported to have frequent episodes of emesis, although the baby has gained weight well and hasn't had any choking episodes.

**BOX 217-4 Case Report 2**

A distraught mother brings her 3-month-old son for evaluation. She describes an episode in which her son turned blue and became limp. A health care worker by training, she relates how she provided rescue breathing before coming to the hospital. A similar episode occurred twice before and required the infant to be hospitalized once. The infant is again hospitalized for further evaluation. Initial diagnostic studies, including

a complete blood count, urinalysis, chest radiograph, electrocardiogram, and upper gastrointestinal series, are all normal. A computed tomography scan of the head is obtained and reveals a left temporoparietal subdural hematoma. A subsequent skeletal survey reveals multiple healing rib fractures with callus formation. Child abuse is suspected, and child protective services are contacted for further investigation.

**BOX 217-5 Evaluating an Infant Who Experienced an Apparent Life-Threatening Event**

The initial basic set of tests that might be considered in infants with no identified cause after initial clinical assessment includes

- Complete blood count
- Basic metabolic panel and ammonia
- Urinalysis
- Electrocardiogram
- Chest radiograph
- Blood culture
- Urine culture

Additional studies that might be considered after an initial period of observation include

- Polysomnogram or pneumogram
- Esophogram and gastroesophageal reflux study
- Modified barium swallow study
- Neuroimaging
- Tests for respiratory pathogens as indicated
- Liver function tests to screen for occult abdominal injury

that contribute to GERD. If GERD is the suspected cause for an ALTE, then a 24-hour pH probe is preferable; however, while up to 89% of infants with an ALTE may have a positive study, only 41% of these infants have a correlating clinical diagnosis. This circumstance highlights the problem of exhaustively testing all infants if the clinical history or physical examination does not suggest a diagnosis. If enough tests are performed, especially when the index of suspicion is low, then the increasing likelihood of false-positive results will diminish the diagnostic use of these studies and unnecessarily increase the risk for iatrogenic complications.

Pediatric polysomnography (PSG) is a multichannel diagnostic study used most commonly to evaluate children for obstructive sleep apnea and to evaluate cardiorespiratory function in infants and children with chronic lung disease or neuromuscular disease when indicated. In comparison, a pediatric pneumocardiogram (also referred to as a *pneumogram* [PNG]) is a 12- to 24-hour recording of breathing effort, heart rate, oxygen level, and airflow to the lungs during sleep. The study is useful in identifying abnormal breathing patterns, with or without bradycardia, especially in premature infants. PNGs are less expensive and can be performed in the home or hospital setting, whereas PSG requires hospitalization, typically overnight, although there are reports that a 4-hour period of monitoring during sleep periods may be sufficient to identify central, obstructive, and mixed apneas. If a

pH probe is used, the relationship between the apneas and GER, if present, can be examined.

When the history and physical examination do not suggest a probable diagnosis for an ALTE, the following studies or interventions are often considered: white blood cell count and blood culture, urinalysis and culture, cerebrospinal fluid analysis and culture, viral antigen and pertussis testing, chest radiograph, neuroimaging, and PSG. Pediatric polysomnography may provide more detailed information about cardiopulmonary abnormalities during sleep and feeding, but is not widely available. An alternative is the PNG, which might detect CA events with oxygen desaturation or bradycardia and could confirm a relationship to acid reflux events if paired with a pH probe monitor. The risk compared to the benefit of routine testing in this population is unknown. However, a single-center study looking at hospitalized patients showed that for many tests the likelihood of a positive result was low and the likelihood of a contributory result was even lower. Routine testing may be warranted in higher-risk groups. For example, a single-center ED study of infants younger than 2 months and with a history of prematurity does suggest in 2.7% of cases occult infections such as UTI, bacteremia, and pertussis.”

Because many victims of child abuse can present with ALTE, a high index of suspicion should be maintained, especially when the history and physical examination do not indicate a likely cause. Although little evidence suggests routine testing in this population, the pediatrician should judiciously consider a dilated funduscopic examination, neuroimaging, toxicology screen, and skeletal survey.

Seizures may account for 5% of ALTEs, and a 5-year follow-up study showed that up to 3.6% of all patients with an ATLE will go on to develop epilepsy; however, routine neurology workup is not indicated in these patients unless traumatic brain injury is suspected. Without suggestive findings in the history or physical examination, the results of tests of chemistries, cerebrospinal fluid, nasopharyngeal aspirates, echocardiogram, and electrocardiogram will likely be unrevealing.

## MANAGEMENT

Simple observation is insufficient. Several studies have demonstrated that significant cardiorespiratory events can be missed by nursing observation accompanying simple, unrecorded cardiorespiratory monitoring and oximetry at the bedside. PSG can also detect obstructive and central respiratory events, although adequate normative data on obstructive sleep apnea in infants are not available. A home PNG by an equipment company is not as effective as a PNG in the hospital where nurses and parents can observe the patient and document movements, feeding, etc. Also, a hospital PNG can easily include esophageal reflux to document any relation between cardiorespiratory events and GER.

Assessments of suspected child abuse should be referred to child protective services and law enforcement. There is no evidence to support routine hospitalization of all patients with ALTEs. The decision to hospitalize infants should be guided by the findings of

the initial assessment along with some special consideration for higher-risk groups (including whether or not there is a responsible adult in the home who has CPR training). Infants whose postmenstrual age is less than 44 weeks are a higher-risk group, particularly if born premature. One study from a tertiary care pediatric hospital showed little benefit in routine hospital admission of infants older than 1 month where there was no clear etiology and the infant was well seeming after an ED evaluation. In another study from an ED, 2.7% of afebrile infants younger than 2 months with a history of prematurity had bacteremia, UTI, or pertussis. However, if the ALTE was not the first episode, the situation requires vigorous stimulation (eg more than light touching, but not shaking) from a reliable pediatrician, or when the initial physical examination reveals an abnormality, then hospitalization with continuous cardiorespiratory monitoring and further evaluation are more likely to be beneficial. The hospital environment may help document recurrent ALTEs, provide time for test results to return, and reveal social concerns indicative of child abuse. For example, continuous cardiorespiratory monitoring with pulse oximetry may detect apnea, bradycardia, and hypoxemia. It is important to note that typical apnea settings of 20 seconds on a cardiorespiratory monitor may miss bradycardia, clinically relevant respiratory pauses (<20 sec), or obstructive and mixed apnea events that lead to hypoxemia. Documentation of apnea, bradycardia, and hypoxemia events in the hospital setting should warrant further evaluation and consultation with a pulmonary specialist.

The benefit to hospitalization must also be weighed against unintended consequences, such as increasing parental anxiety, risk for nosocomial infections, and unnecessary testing or use of hospital resources. If the witnessed event or a review of the history suggests severe cardiorespiratory compromise, then the infant should be admitted to an intensive care unit. Treatment directed at the underlying diagnosis determined by the evaluation should be started—for example, antibiotics for suspected bacterial infection, anticonvulsants for an infant with seizures, and medications for GERD.

A routine PSG is unnecessary but may contribute to a diagnosis in cases where there is significant respiratory compromise, concern for CA, or anatomic abnormalities of the head and neck, or when there has been more than 1 ALTE. At institutions where PSG is not available, home equipment companies may arrange for the data acquisition of respiratory and cardiac events by using a PNG, which an outside consultant reviews. PNGs are unattended studies that collect data on respiratory effort (by using a thoracic impedance monitor), nasal flow, oxygenation, and cardiac rhythm, but not sleep staging, carbon dioxide signal, or abdominal effort. More technical artifacts exist from PNGs because no technician adjusts the leads and maintains adequate signal quality. Because the PSG is more informative, PNGs should be limited to medical centers where PSG is unavailable.

In preparation for discharge home, parents and other caregivers must be taught safe sleeping tips and counseled on CPR. If the child is going home on a

**Figure 217-1** Polysomnographic tracing of a 3-month-old infant with hypoxemia noted on monitoring in hospital for an ALTE. The infant has periodic breathing, with respiratory pauses of much less than 20 seconds (see thoracic and abdominal leads with no flow when respiration stops). Cardiorespiratory monitors routinely sound an alarm only when breathing has ceased for 20 seconds or more, and they would not detect periodic breathing unless the event led to bradycardia with the heart rate below the alarm's limit. This infant has brief pauses in series that lead to hypoxemia; thus, this event denotes pathologic periodic breathing. Polysomnography is able to detect a cause for the hypoxemia that the hospital monitor might not. Treatment would be caffeine to stimulate breathing.

monitor, all caregivers must be trained in how to respond to alarms. The American Academy of Pediatrics (AAP) policy on SIDS stresses the hazards of adults sleeping with an infant in the same bed because of the potential for accidental suffocation. Co-sleeping should be discouraged, because the safest place for an infant to sleep for the first 6 months of life is in a crib in the parents' room. In severe cases requiring CPR or where apneas were demonstrated during hospitalization, especially where there is not a clear etiology, home cardiorespiratory monitoring may help determine when the events have resolved and provide reassurance for the family. The AAP policy statement on apnea, SIDS, and home monitoring notes that an indication for home monitoring may include infants who have had an ALTE. An important point to remember is that episodes of periodic breathing and obstructive

apnea events will not be captured on home cardiorespiratory monitoring unless a secondary effect of these events on heart rate occurs (Figure 217-1). The cardiorespiratory monitor results should be reviewed by a pediatrician or specialist who is trained in their review, and the physician should establish a specific plan for periodic review. In most cases, results should be reviewed monthly if the guardian has no concerns about the baby or sooner if the guardian reports 1 or more significant events. The CHIME Study Group suggested that healthy term and premature infants may have apnea events and that these events become rare by 43 weeks' postmenstrual age. Monitoring may be discontinued once no further physiologically significant events have occurred and home monitoring shows no further objective evidence of pathologic events for at least 6 weeks. If obstructive apnea is

identified as a cause for an ALTE, then repeat PSG may be necessary to determine when and if intervention is needed.

Long-term outcomes for infants with an unexplained ALTE are unpredictable. Infants with a severe event who require resuscitation and experience a recurrent ALTE or a seizure disorder have a risk for death higher than 25%. However, other studies have reported normal cognitive and behavior outcomes up to 10 years after an ALTE.

## SUMMARY

An ALTE is a common, nonspecific disorder of the young infant that is usually self-limited, although it is potentially serious and life threatening. By understanding the definition, and by eliciting a complete history and performing a thorough physical examination, the physician can focus on determining the best laboratory and imaging studies to diagnose the underlying cause of the event. If a benign cause is not evident, a period of observation with cardiorespiratory monitoring in the hospital is necessary to gather additional information and direct appropriate diagnostic studies. Education and guidance should be provided to the guardian, with monitoring in the home setting after hospitalization to detect the infrequent recurrence of ALTEs.

### WHEN TO REFER

- When home CR monitoring is considered after a severe event requiring CPR
- Suspected seizure disorder
- Suspected hypoxemia or hypercarbia
- Suspected central, obstructive, or mixed apnea
- Suspected cardiac dysrhythmia
- Vascular ring identified
- Congenital craniofacial anomalies with suspected obstructive apnea
- Evidence of child abuse
- Atypical manifestation

### WHEN TO ADMIT

- History of prematurity
- Witnessed apnea (central or obstructive) with oxygen desaturation or bradycardia by medical staff
- Age younger than 2 months or 48 weeks post-menstrual age
- Family history of SIDS
- Suspected child abuse
- Multiple ALTEs
- Suspicion for central or obstructive apnea

## Chapter 218 ASTHMA

Chitra Dinakar, MD

## EPIDEMIOLOGIC FEATURES

Asthma is a chronic inflammatory condition of the airways characterized by episodic airway obstruction. Of the 25 million people in the United States with asthma, almost 7.1 million are children. The prevalence of childhood asthma, although steady since 1996, remains at historically high levels, with 13.1% of

children diagnosed as having asthma during their lifetime. Asthma is a serious public health problem resulting in an annual cost of nearly \$56 billion. It is the third-ranking cause of hospitalization among children younger than age 15 years, and among the most common causes of childhood emergency department (ED) visits (593,000 ED visits in 2006). Asthma can cause significant morbidity. Every day in the United States, 44,000 people have an asthma exacerbation, 36,000 children miss school because of asthma, and 27,000 adults miss work because of asthma. Most asthma care is delivered by primary care physicians, with only 1 in 5 children seeking specialty care. Visits to primary care settings (physician offices and hospital outpatient departments) represent most health care use for persons with asthma.

Risk factors and triggers associated with childhood asthma have been identified. Although the most common trigger of wheezing in young children is viral respiratory tract infection, the strongest single predictor for wheezing continuing into asthma is atopy. A significant association exists between serum immunoglobulin E (IgE) level and the development and severity of asthma. The risk for asthma is increased by certain allergens, such as cockroach allergen among children with asthma in the inner city, and irritant exposures such as tobacco smoke. Although more than 100 candidate genetic loci have been identified based on epidemiologic linkage studies, the more consistent associations have been with the pro-allergic loci (interleukin-4 gene cluster on chromosome 5), chromosome 5q31 (bronchial hyperresponsiveness), chromosome 11q13 (high-affinity IgE receptors), and chromosome 14q (T-cell antigen receptor). Other studied genes include ADAM-33 (member of the metalloproteinase family), the gene for the prostanoid DP receptor, and receptor polymorphisms causing biologic variations in response to  $\beta$ -agonist medications.

Racial, ethnic, and socioeconomic disparities have been identified as factors relating to the burden of the disease. Blacks have higher rates of asthma ED visits (330% higher), hospitalizations (220% higher), and deaths (180% higher) than whites. The rate of asthma among Puerto Ricans is 113% higher than among non-Hispanic whites and 50% higher than among non-Hispanic blacks.

Many pediatricians and primary care physicians do not realize that childhood asthma can have fatal outcomes (2.3 asthma-related deaths per 1 million children; a total of 167 deaths in 2005). Of great concern is that many of these fatal outcomes occur in children viewed as having mild disease. Risk factors associated with death from asthma include the following:

1. History of sudden severe exacerbations
2. Prior admissions to an intensive care unit
3. Prior intubation for asthma
4. Two or more hospitalizations or 3 or more ED visits in a 12-month period
5. Use of more than 1 canister per month of inhaled short-acting  $\beta$ -agonist
6. Chronic use of oral corticosteroids
7. Difficulty perceiving airflow obstruction or its severity

## PATHOPHYSIOLOGIC FEATURES

The exact cause of childhood asthma is not known and is best understood as having derived from a complex gene-environment interaction. The combination of environmental exposures and genetic-biologic susceptibilities causes pathogenic changes in the airways. After asthma develops, ongoing exposures increase the risk for exacerbations.

Asthma is, therefore, often described as a lung disease characterized by 3 features.

1. *Airway obstruction* that is at least partially reversible by bronchodilator treatment
2. *Airway hyperreactivity or hyperresponsiveness* to a variety of external stimuli. This is considered a hallmark feature that correlates well with severity.
3. *Chronic inflammation* characterized by mast cell activation, inflammatory cell infiltration by eosinophils, and helper T-cell type 2 ( $T_H2$ ) lymphocytes and neutrophils (the latter is seen in sudden-onset fatal asthma exacerbations). These features result in anomalous tissue repair and airway remodeling.

The symptoms of asthma are caused by airflow obstruction resulting from the cumulative effects of smooth muscle constriction around airways; airway wall edema caused by increased vascular permeability; mucus hypersecretion and intraluminal mucus accumulation caused by goblet cell hyperplasia; inflammatory cell infiltration of the submucosa, causing disruption of the bronchial epithelium; and smooth muscle hypertrophy and basement membrane thickening secondary to type IV collagen deposition from increased fibroblast proliferation. This deposition may cause airway remodeling, which clinically exhibits as nonreversible obstructive lung disease. Many of these pathologic changes are reflected in the sputum, such as Charcot-Leyden crystals (eosinophil remnants), Curschmann spirals (airway lumen casts of exudate), and Creola bodies (clumps of sloughed epithelial cells). Children with fatal asthma usually exhibit marked pathologic changes in the segmental and subsegmental bronchi with involvement of the small airways down to, but usually sparing, the respiratory bronchioles. Multiple cytokines, including leukotrienes, and IgE antibodies, have been implicated in disease severity and progression, and impaired glutathione homeostasis, a biomarker of oxidant stress, has been associated with airway injury in severe asthma.

The most common triggers in childhood (Box 218-1) include viral respiratory infections, exercise, irritants such as tobacco smoke, indoor and outdoor allergens, and a change in the weather, particularly cold air. Stress and emotional expression such as laughter and anger have been associated as triggers as well. In the presence of symptoms that seem to be worse at night or with reclining posture, the pediatrician may consider the possibility of sinusitis or gastroesophageal reflux as contributory comorbid clinical conditions. However, it should be noted that a recent multicentered trial demonstrated that adding prescription acid controllers to standard inhaled steroid treatment does not improve asthma symptoms or control in children with undetected or "silent" gastroesophageal reflux.

An allergic asthma exacerbation is biphasic, with an early phase or immediate response occurring within

**BOX 218-1 Factors That Exacerbate Asthma**

- Viral respiratory tract infections
- Environmental allergens in sensitized individuals
  - Outdoor allergens (eg, seasonal allergens such as tree pollen, grass pollen, weed pollen, molds)
  - Indoor allergens (eg, animal dander, dust mites, cockroach, indoor molds, mouse)
- Irritants
  - Environmental tobacco smoke
  - Air pollutants (eg, ozone, sulfur dioxide)
  - Particulate matter (eg, wood or coal burning smoke)
  - Mycotoxins
  - Endotoxin
  - Dust
  - Strong odors or fumes (eg, perfumes, hair sprays, cleaning agents, incense sticks, scented candles)
- Occupational exposure (eg, farm and barn exposure, formaldehyde, cedar, paint fumes, others)
- Cold, dry air
- Exercise
- Emotions: crying, laughter, hyperventilation
- Comorbid conditions (eg, rhinitis, sinusitis, gastroesophageal reflux, nasal polyps)

minutes of trigger exposure characterized by bronchospasm and bronchoconstriction. This episode is followed physiologically by an immediate drop in forced expiratory volume in 1 second (FEV<sub>1</sub>), which returns to normal within a few hours after exposure. A second, more severe drop (late-phase inflammatory) occurs later, approximately 6 to 24 hours after exposure to the trigger. The initial reaction tends to respond well to inhaled bronchodilator agents, whereas the late bronchoconstriction responds less well to inhaled  $\beta$ -agonists and requires the use of corticosteroids. Corticosteroids are, therefore, given early during a severe asthma exacerbation to avoid or mitigate the second-stage relapse.

Within minutes of an exposure to a trigger, IgE molecules on the surface of mast cells bind the inciting allergen, leading to mast cell degranulation and release of mediators, including histamine, prostaglandin D<sub>2</sub> (PGD<sub>2</sub>), and cysteinyl leukotrienes (LTC<sub>4</sub>, D<sub>4</sub>, and E<sub>4</sub>). These mediators cause airway smooth muscle contraction and stimulation of reflex neural pathways that are largely reversible by  $\beta$ -agonist administration. Within hours of the initial trigger, the late-phase response occurs triggered by the influx of inflammatory and immune cells, particularly the eosinophils, basophils, neutrophils, helper T cells, and dendritic cells. The mast cells and eosinophils are key players in the inflammatory cascade. In addition to producing bronchoconstricting mediators, mast cells also store and release tumor necrosis factor- $\alpha$ , which is important in the recruitment and activation of inflammatory cells and in modifying the function and growth of airway smooth muscle. Eosinophils release tissue-damaging

enzymes and proteins such as major basic protein, eosinophil cationic protein, eosinophil-derived neurotoxin, and eosinophil peroxidase.

The T-cell lymphocyte population in the asthmatic airway is characterized by the T<sub>H</sub>2 of lymphocytes that generates a specific panel of cytokines, including IL-3, IL-4, IL-5, IL-13, and granulocyte-macrophage colony-stimulating factor (GM-CSF) when stimulated with antigen. The T<sub>H</sub>2 lymphocytes also express the chemokine receptors (CCR4 and CCR8) and the chemoattractant receptor like molecule (CRTH2), a receptor for PGD<sub>2</sub>, suggesting potential signaling and interactions between the mast cell, eosinophils, and T<sub>H</sub>2 cells that promulgate airway inflammation. Basophils, in addition to producing histamine and leukotrienes, are potent producers of IL-4 and IL-13 cytokines, exceeding levels produced by T cells. The innate immune system (dendritic cells, neutrophils, toll-like receptors) also is postulated to play an important role in the development of allergic airway inflammation.

Another important pathway in the pathophysiologic features of allergic asthma is the arachidonic acid pathway, which is responsible for the production of prostaglandins by cyclooxygenase or leukotrienes through the 5-lipoxygenase pathway. Mast cells and eosinophils synthesize significant amounts of LTC<sub>4</sub>, LTD<sub>4</sub>, and LTE<sub>4</sub>. Cysteinyl leukotrienes are responsible for significant bronchoconstriction 100 to 1,000 times greater than histamine and contribute to increased mucus secretion, decreased mucus clearance, eosinophil infiltration, and eosinophil activation.

**DIAGNOSING ASTHMA IN CHILDREN**

The most common symptoms that arouse a suspicion of asthma are intermittent and repetitive episodes of cough and noisy breathing or wheezing triggered by respiratory infections, allergen or irritant exposure, exercise, or play, with symptoms often awakening the child at night. Older children may report shortness of breath and chest tightness, particularly associated with physical activity. Nonspecific symptoms may include self-imposed limitation of physical activities, general fatigue, and difficulty keeping up with peers. Recurrent “croup” in an older child or frequent “clinical pneumonias” or “bronchitis” may also alert the pediatrician to consider evaluating for possible asthma. To make the diagnosis of asthma, the pediatrician must determine the following:

1. The child has recurrent episodic symptoms of airway obstruction, such as cough, wheezing, shortness of breath, or chest tightness.
2. Airway flow obstruction or airflow limitation is at least partially reversible by administration of a bronchodilator. In older children and adults, spirometry before and after bronchodilator use can serve as an ambulatory test to delineate bronchial hyperresponsiveness. In a younger child, a positive clinical response to an inhaled  $\beta$ -agonist may be useful to determine partial reversibility.
3. Alternative diagnoses are excluded.

Noninvasive, bedside demonstration of airway inflammation, as with exhaled nitric oxide testing recently approved by the US Food and Drug Administration

(FDA), may provide additional supplementary information regarding the diagnosis and severity of asthma.

A detailed medical history is the first step in establishing the diagnosis. The history should focus on the nature and frequency of symptoms, response to medications, precipitating factors, and concomitant atopic features, if any. The physical examination should focus on the upper respiratory tract, chest, and skin. Signs of allergic disease, such as eczematous skin, erythematous conjunctiva with cobblestoning, allergic shiners, Denny Morgan lines, allergic salute, allergic nasal crease, pale boggy turbinates, rhinorrhea, and polyps, should be noted. A transverse nasal crease and features of atopy are tell-tale signs of allergic diathesis. Nasal polyps in a younger child may raise the suspicion of cystic fibrosis. The chest examination may be unremarkable in children with asthma, although dyspnea with speech and with exertion, characterization of breath sounds, and measurement of the inspiration-to-expiration ratio may be of value.

Unfortunately, the diagnosis of asthma in a child is often delayed or the severity underestimated. Underdiagnosis is frequent in children because pediatricians commonly use labels such as reactive airway disease, recurrent bronchitis, or wheezy bronchitis for asthma. Use of this terminology is not advisable and may hinder appropriate diagnosis and therapy. Symptoms and signs that are not consistent with asthma, including failure to thrive, cyanosis, and clubbing, should alert the pediatrician to alternative diagnoses such as ciliary dyskinesia or cystic fibrosis. Chronic cough alone may also be a manifestation of asthma, especially in young children, leading to the term *cough-variant asthma*. The diagnosis of cough-variant asthma may be made by monitoring peak expiratory flow or methacholine inhalation challenge if applicable, to clarify whether there is bronchial hyperresponsiveness consistent with asthma. Use of bronchodilators on a trial basis may be helpful to demonstrate reversibility of the bronchospasm and improvement in symptoms. If there is clinical improvement, then treatment should follow the stepwise approach to long-term management of asthma. However, cough-variant asthma is as often overdiagnosed as it is underdiagnosed; therefore, an alternate diagnosis (eg, allergic rhinitis or chronic sinusitis with postnasal drainage, infectious causes such as pertussis, and psychogenic or habit cough) should be sought if symptoms do not respond to traditional asthma therapies.

### Laboratory Evaluation

Current national and international guidelines recommend evaluation for potential inhalant allergen triggers, particularly in those with persistent asthma. Assessment of sensitivity to environmental allergens using in vivo (skin testing) or in vitro (specific IgE) methods followed by clinical correlation may help identify allergic predisposition and triggers and suitability to receive targeted therapies. Sputum and nasal eosinophil evaluation is not commonly performed in children. A baseline chest radiograph may help exclude other conditions that mimic asthma, such as foreign body aspiration or vascular ring, but routine and repetitive chest radiographs during asthma exacerbations are not

recommended. White cell count and differential and quantitative immunoglobulins and sweat chloride when indicated may be of value to rule out immune dysregulation and cystic fibrosis, respectively.

### Pulmonary Function Testing

Assessment of spirometric measures of airflow and lung volumes during forced expiratory maneuvers is strongly recommended as standard of care for asthma diagnosis and monitoring. Prebronchodilator and postbronchodilator spirometry, particularly in children who are poor perceivers of airflow, is strongly recommended to confirm the diagnosis and classify disease severity and to provide insight into the pathophysiologic processes. Spirometry should be performed on any child 5 years of age or older who is capable of performing this test. Objective measures of lung function enable the pediatrician to do the following:

1. Diagnose airflow obstruction, as well as reversibility.
2. Monitor changes over time, including daily variations.
3. Manage exacerbations, including those resulting in severe airway obstruction.

Spirometry is generally preferred to peak flow monitoring for the diagnosis of asthma because peak flow measurements primarily assess large airway function, require establishment of individual baseline values to facilitate meaningful interpretation, and are effort-dependent maneuvers. Spirometry should be performed by trained personnel before a child inhales a short-acting bronchodilator and again 15 to 20 minutes afterward.

This test helps determine the presence and degree of airflow obstruction of large and small airways and whether the airflow obstruction is reversible. The key measurements assessed are the forced vital capacity (FVC), FEV<sub>1</sub>, forced midexpiratory flow rate (FEF<sub>25-75</sub>), and an examination of the flow volume loop. Reproducible spirometric measurements (FEV<sub>1</sub> values within 5% on 3 attempts) are an indicator of test validity. A baseline spirometry should also be performed once a year during follow-up evaluations. In an asthmatic child, airway obstruction results in reduced airflow with forced exhalation and smaller midexpiratory air flow rates. The FEV<sub>1</sub> should be adjusted for the hyperinflation typically seen in asthma and, in general, an FEV<sub>1</sub>/FVC ratio of less than 85% predicted is indicative of the presence of airflow obstruction. Low FEV<sub>1</sub>, as a percentage of predicted norms, is one of the criteria used to assign severity in asthma. Because other conditions can cause airflow obstruction, demonstration of the presence of an improvement in FEV<sub>1</sub> of more than 12% and more than 200 mL from baseline and 10% or greater of predicted FEV<sub>1</sub> after inhaled bronchodilator use is considered evidence of reversibility consistent with asthma. It should be noted that children with asthma have been reported to have much better baseline lung function compared to adults with asthma; therefore, the spirometry can occasionally be normal in a clinical scenario suggestive of asthma. Recent observations questioned the degree of improvement that signifies the presence of reversible airway hyperresponsiveness in children with asthma,

with studies suggesting poor sensitivity associated with the commonly used 12% cutoff in children with asthma compared with adults. Lesser amounts of reversibility may be indicative of airway hyperresponsiveness in children with asthma because there is so much variability of this test in children.

Provocative testing used to demonstrate bronchial hyperresponsiveness, such as exercise challenges, methacholine, cold air, and most recently, mannitol challenges, is performed only when the determination of asthma is difficult despite routine evaluation.

Assessment of exhaled nitric oxide, a measure of airway inflammation in allergic asthma, is gaining support as a tool in aiding the management of asthma.

Peak flow meters are inexpensive home-use devices that lack the sensitivity for diagnostic use, and reference values vary widely and according to the brand. Peak flow zones are established after the child has the opportunity to monitor daily (or twice daily) for 2 weeks or more to establish his personal best. Peak flow monitoring at home can, however, be useful because it can help determine whether airway narrowing is occurring before children become symptomatic; additionally, it can help the pediatrician to do the following:

1. Monitor the effect of medication addition or withdrawal.
2. Determine when to seek help.
3. Determine the effect of triggers.
4. Determine changes in lung function.

## DIFFERENTIAL DIAGNOSIS

A common medical school teaching is that “all that wheezes is not asthma.” Common asthma imposters such as gastroesophageal reflux and sinusitis can be challenging to diagnose in children. Masqueraders of asthma can be approached anatomically as upper respiratory conditions, including allergic or chronic rhinosinusitis and tonsillar or adenoidal hypertrophy; middle respiratory tract conditions, including foreign body aspiration, vocal cord dysfunction, airway lesions such as airway stenosis, tracheal webs or tracheobronchomalacia, vascular rings, mediastinal masses, and vocal cord dysfunction or paralysis; or lower respiratory tract conditions, such as viral bronchiolitis, bronchiectasis, immotile cilia syndrome, hypersensitivity pneumonitis, interstitial pneumonias, bronchopulmonary aspergillosis, pulmonary edema, pulmonary eosinophilic disorders, cystic fibrosis, pneumonia, tuberculosis, and adverse effects of medications such as angiotensin-converting enzyme inhibitors. It is important to note that many of these latter conditions may coexist with and exacerbate the severity of asthma.

## RISK FACTORS FOR ASTHMA

Hypotheses to explain the increased frequency of asthma include improved hygiene (“hygiene hypothesis”), increased indoor air pollution, greater frequency of early-onset respiratory viral infections, enhanced host susceptibility, and improved awareness and recognition of asthma. In most children with asthma, the onset of symptoms occurs before 5 years of age.

However, of all the preschoolers who wheeze (50%), only a minority (20%) continue to have persistence of asthma in late childhood. Risk factors predicting the persistence of asthma have been identified based on studies of birth cohorts. A popular index used frequently is the modified asthma predictive index, which includes major criteria, such as parental history of asthma, atopic dermatitis, and inhalant allergen sensitization, and minor criteria, such as allergic rhinitis, wheezing apart from colds, eosinophilia at or above 4%, and food allergen sensitization. Symptom-based phenotypes of asthma classify wheezing into 2 main types—episodic (viral) wheeze (wheezing during discrete time periods only, usually associated with common viral respiratory tract infections) and multitrigger wheeze (wheezing during discrete exacerbations and between episodes; triggers include viruses, allergens, exercise, and environmental irritants and pollutants).

## CLASSIFYING ASTHMA SEVERITY AND CONTROL IN CHILDREN

The National Asthma Education and Prevention Program Expert Panel Report 3 (EPR3) was published in the latter part of 2007. A key component of the new guidelines emphasizes asthma control in addition to asthma severity.

Severity is the intrinsic intensity of the disease and is emphasized for initiating therapy. The 2 general categories are “intermittent” and “persistent” asthma, with the latter further subdivided into mild, moderate, and severe. Asthma severity is best assessed during a child’s initial evaluation and when the child is not using a controller medication. When classifying asthma severity into 1 of the 4 classifications, the presence of a single feature is sufficient to categorize the child in the most severe applicable category. Asthma control represents the degree to which manifestations of asthma are minimized and the goals of therapy are met, and should be used as a guide to either maintain or adjust therapy. Responsiveness refers to the ease with which prescribed therapy achieves asthma control.

Attainment of optimal asthma control necessitates monitoring control in multiple domains and adjusting therapy. Asthma control is classified into 3 categories—well controlled, not well controlled, and very poorly controlled. The degree of control can change over time; thus, constant review of symptoms and treatment every 1 to 6 months is helpful. Apart from the assessment of severity and control, the predisposition to risk for exacerbations should also be kept in mind. For instance, a child with intermittent asthma may not need daily controller medication based on the initial assessment of severity, but the child may still have an unexpectedly severe exacerbation triggered by, for example, a viral infection. This would not necessitate the child requiring regular controller medication, but might necessitate rapid escalation of therapy or addition of a controller medication during the high-risk season. Therefore, children with intermittent asthma who are experiencing severe exacerbations requiring hospitalization or intensive care may require further evaluation and referral to an asthma specialist.

## ASTHMA MANAGEMENT STRATEGIES

### Goals of Asthma Therapy

The goals of asthma therapy may be categorized into 2 domains—reduction in impairment and reduction of risk.

Impairment refers to the intensity and frequency of asthma symptoms and the degree to which the child is limited by the symptoms. Specific goals for reducing impairment include the following:

- Freedom from frequent or troublesome symptoms of asthma, especially including those that disturb sleep
- Minimal need (<2 times a week) for inhaled short-acting  $\beta$ -agonists (SABAs) to relieve symptoms
- Optimization of lung function
- Maintenance of normal daily activities, including work, school, participation in athletics, and physical activity
- Satisfaction with the asthma care on the part of the patient and family

Risk pertains to adverse outcomes associated with asthma and its treatment. Specific goals for reducing risk include the following:

- Prevention of recurrent exacerbations and need for ED visit or hospital care
- Prevention of reduced lung growth and loss of lung function
- Optimization of pharmacotherapy with minimal or no adverse effects

Appropriate asthma management includes 4 components of care.

1. Regular assessment and monitoring
2. Patient education and partnership
3. Control of aggravating factors
4. Pharmacotherapy

### Component 1: Regular Assessment and Monitoring

Assessment of asthma control should not be based solely on individual single measurements and limited interactions, but rather on a combination of multiple parameters, including FEV<sub>1</sub>, peak expiratory flow, daily symptom scores,  $\beta_2$ -agonist use, nocturnal symptoms, and activity limitations. Several recommended standardized questionnaires to assess asthma control include the Asthma Therapy Assessment Questionnaire, the Asthma Control Questionnaire, the Asthma Control Test, and the asthma control score. Key elements captured are the child's recall of symptoms, physical activity, quality of life, need for rescue medications in the past 2 to 4 weeks, and pulmonary function. Objective measurements of lung function include spirometry and peak flow monitoring. The EPR3 guidelines have criteria for 3 age groups—0 to 4 years, 5 to 11 years, and 12 years and older—for the evaluation of both severity (Tables 218-1 and 218-2) and control (Tables 218-3 and 218-4).

The parameters related to assessing asthma control should be checked at every visit. Although, typically, most medical visits for asthma are for urgent care, effective asthma management requires a proactive, preventative approach because it is a chronic disease. Therefore, follow-up visits are recommended every 2 to 6 weeks until good asthma control is achieved and

then 2 to 4 times per year, depending on the attainment of control. Domains assessed at each visit should include the following: signs and symptoms, pulmonary function, quality of life, exacerbations, adherence to treatment, medication side effects, and patient satisfaction with care.

### Component 2: Patient Education and Partnership

Patient education should be geared to empowering children with self-management skills. The children and families should be taught basic facts about asthma, preferably using visual props such as models and colored pictures. Topics should include the following:

- Differences between normal and asthmatic airway
- The link between airway inflammation, hyperreactivity, and bronchoconstriction
- Identification and abatement of triggers
- Role and mechanism of action of long-term controller and quick reliever medications (preferably using patients' own inhalers, demonstration devices, or color pictures)
- Instructions on daily and step-up medication regimens in the form of written asthma action plans
- Practical instructions on being aware of the amount of doses left in the inhaler, correct technique of inhaler use along with spacer, and reinforcement on need to take the daily medication even when the child is asymptomatic

Individualized goals and priorities of asthma management should be set in partnership with the child and family (Box 218-2). Provide an asthma action plan with written instructions for daily management, as

### BOX 218-2 Checklist of Asthma Management Strategies

- Set individualized goals of asthma management.
- Provide effective education that includes
  - Basic facts about asthma
  - Differences between normal and asthmatic airway, preferably using models
  - Links between airways inflammation, hyperreactivity, and bronchoconstriction
  - Long-term controller and quick reliever medications (preferably using patient's inhalers or color pictures)
- Teach, demonstrate, and have patient show proper technique for
  - Inhaled medication use (spacer use with MDI)
  - Peak flow meter (optional)
- Tailor therapy to severity and patient preference.
- Proactively seek out and address concerns about potential adverse effects of medications.
- Explore and manage asthma triggers.
  - Environmental exposures
  - Comorbid conditions
- Provide asthma action plan.
  - Involve patient and family.
  - Also provide asthma plan for school.

Table 218-1 Classifying Asthma Severity and Initiating Therapy in Children

PERSISTENT

COMPOONENTS OF SEVERITY					AGES		AGES		AGES		AGES	
					0-4		5-11		0-4		5-11	
Impairment	Symptoms	≤2 days/week		>2 days/week but not daily		Daily		Throughout the day				
	Nighttime awakenings	0	≤2x/month	1-2x/month	3-4x/month	3-4x/month	>1x/week but not nightly	>1x/week	Often 7x/week			
	Short-acting β <sub>2</sub> -agonist use for symptom control	≤2 days/week		>2 days/week but not daily		Daily		Several times per day				
	Interference with normal activity	None		Minor limitation		Some limitation		Extremely limited				
	Lung Function	N/A	Normal FEV <sub>1</sub> between exacerbations >80%		N/A	>80%	N/A	60-80%	N/A	<60%		
Risk	• FEV <sub>1</sub> (predicted) or peak flow (personal best)	>85%		>80%		75-80%		<75%				
	• FEV <sub>1</sub> /FVC											
	Exacerbations requiring oral systemic corticosteroids (consider severity and interval since last exacerbation)	0-1/year (see notes)		≥2 exacerbations in 6 months requiring oral systemic corticosteroids, or ≥4 wheezing episodes/1 year lasting >1 day AND risk factors for persistent asthma		≥2x/year (see notes) Relative annual risk may be related to FEV <sub>1</sub>						

**Table 218-1** Classifying Asthma Severity and Initiating Therapy in Children—cont'd

		PERSISTENT							
		INTERMITTENT		MILD		MODERATE		SEVERE	
		AGES 0-4	AGES 5-11	AGES 0-4	AGES 5-11	AGES 0-4	AGES 5-11	AGES 0-4	AGES 5-11
COMPONENTS OF SEVERITY		Step 1 (for both age groups)	Step 2 (for both age groups)	Step 2 (for both age groups)	Step 3: medium-dose ICS option and consider short course of oral systemic corticosteroids	Step 3 and consider short course of oral systemic corticosteroids	Step 3 and consider short course of oral systemic corticosteroids	Step 3 and consider short course of oral systemic corticosteroids	Step 3: medium-dose ICS option OR step 4 and consider short course of oral systemic corticosteroids
Recommended Step for Initiating Therapy (See Table 218-5 for treatment steps. <sup>a</sup> )		In 2–6 weeks, depending on severity, evaluate level of asthma control that is achieved. <ul style="list-style-type: none"> <li>Children 0–4 years old: If no clear benefit is observed in 4–6 weeks, stop treatment and consider alternative diagnoses or adjusting therapy.</li> <li>Children 5–11 years old: Adjust therapy accordingly.</li> </ul>							

FEV<sub>1</sub>, forced expiratory volume in 1 second; FVC, forced vital capacity; ICS, inhaled corticosteroids; ICU, intensive care unit; N/A, not applicable.

<sup>a</sup>The Stepwise Approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.

- Level of severity is determined by both impairment and risk. Assess impairment domain by caregiver's recall of previous 2–4 weeks. Assign severity to the most severe category in which any feature occurs.
- Frequency and severity of exacerbations may fluctuate over time for patients in any severity category. At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma severity. In general, more frequent and severe exacerbations (eg, requiring urgent, unscheduled care, hospitalization, or ICU admission) indicate greater underlying disease severity. For treatment purposes, patients with  $\geq 2$  exacerbations described above may be considered the same as patients who have persistent asthma, even in the absence of impairment levels consistent with persistent asthma.

\*ACQ values of 0.76–1.4 are indeterminate regarding well-controlled asthma.  
EIB, exercise-induced bronchospasm; ICU, intensive care unit.

- The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
- The level of control is based on the most severe impairment or risk category. Assess impairment domain by patient's recall of previous 2–4 weeks and by spirometry or peak flow measures. Symptom assessment for longer periods should reflect a global assessment, such as inquiring whether the patient's asthma is better or worse since the last visit.
- At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma control. In general, more frequent and intense exacerbations (eg, requiring urgent, unscheduled care, hospitalization, or ICU admission) indicate poorer disease control. For treatment purposes, patients who had  $\geq 2$  exacerbations requiring oral systemic corticosteroids in the past year may be considered the same as patients who have not-well-controlled asthma, even in the absence of impairment levels consistent with not-well-controlled asthma.

ATAQ = Asthma Therapy Assessment Questionnaire

ACQ = Asthma Control Questionnaire

ACT = Asthma Control Test

Minimal Important Difference: 1.0 for the ATAQ; 0.5 for the ACQ; not determined for the ACT.

#### Before step up in therapy:

- Review adherence to medication, inhaler technique, environmental control, and comorbid conditions.
- If an alternative treatment option was used in a step, discontinue and use the preferred treatment for that step.

Adapted from National Heart, Lung, and Blood Institute. *National Asthma Education and Prevention Program Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma*. US Department of Health and Human Services; 2007.

well as a plan for asthma exacerbations. While formulating the plan, proactively seek out and address concerns about potential adverse effects of medications. The therapy should be kept as simple as possible by limiting the number of medications and doses. If children cannot adhere to a medication regimen, investigate the reasons for their nonadherence. The child and caretaker should be encouraged to demonstrate proper technique for inhaled medication use (eg, spacer use with metered dose inhaler [MDI]) and peak flow meter (optional).

The correct asthma medication regimen and administration technique should be reinforced and evaluated. The pediatrician should establish patient priorities on an individual basis and enlist family and peer support to ensure the asthma action plan is implemented. Physical activity should be encouraged by using the appropriate medications to prevent exercise-induced symptoms and by allowing students to carry and administer medication (such as SABAs) at school with parent and physician approval. Physicians should ensure that teachers and school personnel understand the plan for each child with asthma. Families, teachers, and pediatricians should be concerned if  $\beta$ -agonist use is greater than 1 MDI canister per month, if controller medication refills are occurring one-half as often as prescribed, or if the child complains that  $\beta$ -agonists do not seem to help as much as they used to.

It is important to remember that adherence to asthma medication regimens tends to be suboptimal, with reported rates of nonadherence ranging from 30% to 70%. Factors affecting adherence include medication-related factors, patient variables, and physician factors. Medication characteristics such as taste, dosing schedule, difficulties with devices, side effects, and expense are critical. Patient variables such as health beliefs, misperception of disease severity, misunderstanding instructions, fear of side effects, dissatisfaction with health care professionals, forgetfulness, and complacency can affect the management of disease. Physician factors such as poor communication, failure to monitor patients regularly, and incorrect medication and dosage need to be addressed. One critical step to improve adherence is to promote open communication and establish the goals of therapy in collaboration with the child. The pediatrician should be friendly and attentive. All attempts should be made to identify reasons for nonadherence, address concerns, and allay fears. The child should be encouraged and praised for successes. The regimen should be simplified, and children should be educated in an interactive manner at their level of understanding.

### Component 3: Control of Aggravating Factors

Modifiable factors that worsen asthma include both environmental exposures (infectious, allergic, and irritant) and comorbid conditions (Box 218-1). See the earlier section, Pathophysiologic Features, for the most common types of triggers in childhood. Because most children with asthma have an allergic component to their disease, measures to explore and mitigate environmental exposures, when possible, are recommended.

Reliable and patient-friendly educational handouts may be found at some of the sources listed in Tools for Practice at the end of this chapter. It should be noted that, in children with uncontrolled asthma and no overt symptoms of gastroesophageal reflux, treatment with proton pump inhibitors does not help.

### Component 4: Pharmacotherapy

A stepwise approach to asthma pharmacotherapy focuses on minimizing impairment and risk with the goals of relieving obstruction and treating underlying inflammation. The initial therapy is chosen based on degree of asthma severity, and subsequent adjustments are made based on assessment of control and responsiveness to therapy. The key objective of this approach is to distinguish those with persistent asthma requiring daily anti-inflammatory medication from those with intermittent asthma that can be managed with SABA rescue medication as needed. The type and amount of controller medications required are determined by the degree of severity and control. The National Heart, Lung, and Blood Institute (NHLBI) guidelines elegantly lay out the stepwise approach (steps 1–6) to asthma management based on initial assessment of asthma severity and age of the child (<4 years, 5–11 years, and >12 years). Tables 218-5 and 218-6 serve to outline their approach and serve as a ready reference.

Asthma medications are defined and categorized in 2 ways—*relief medication* for quick relief of acute symptoms and exacerbations, and *controller medication* for long-term control of the underlying pathophysiologic mechanism of asthma. Quick-relief medications include SABAs, systemic corticosteroids, and anticholinergic agents. Long-term controller medications include inhaled corticosteroids (ICS), combination ICS and long-acting  $\beta$ -agonists (ICS-LABA), leukotriene receptor antagonists (LTRA), and others that are less commonly used, such as theophylline, cromolyn, and other steroid-sparing medications.

The preferred therapy for children with persistent asthma is daily ICSs, either as monotherapy or in combination with adjunctive therapy. Alternative medications for mild persistent asthma (step 2 therapy) include LTRA (montelukast) and, rarely, cromolyn and theophylline (for older children). For children younger than 4 years with moderate to severe persistent asthma, medium-dose ICS therapy is recommended. Combination therapy of medium-dose ICS-LABA is recommended only for step 4 or higher levels of uncontrolled asthma. Combinations of medium-dose ICS with LTRA may also be considered for step 4 or higher treatment. Options for children with severe persistent asthma (steps 5 and 6) include ICS-LABA combinations, long-term oral steroids, and omalizumab if they are older than 12 years of age. Allergen immunotherapy may be considered for children older than 5 years of age requiring steps 2–4 care.

When control is achieved and sustained for 3 months or more, stepping down to minimum required dose to maintain control is recommended. If control is not attained, the therapy may be increased by 1 step if not well controlled, or by 2 steps if asthma is very poorly controlled, with close monitoring.

**Table 218-5** Stepwise Approach for Managing Asthma Long Term in Children, 0–4 Years of Age and 5–11 Years of Age**CHILDREN 0–4 YEARS OF AGE**

Step down if possible (and asthma is well controlled at least 3 months)		Assess control		Step up if needed (first check inhaler technique, adherence, environmental control, and comorbid conditions)			
Intermittent Asthma		Persistent Asthma: Daily Medication					
		Consult with asthma specialist if step 3 care or higher is required. Consider consultation at step 2.					
		STEP 1	STEP 2	STEP 3	STEP 4	STEP 5	STEP 6
Preferred		SABA PRN	Low-dose ICS	Medium-dose ICS	Medium-dose ICS + LABA or Montelukast	High-dose ICS + LABA or Montelukast	High-dose ICS + LABA or Montelukast + Oral corticosteroids ICS
Alternative			Cromolyn or Montelukast				
Quick-Relief Medication		<b>Each Step: Patient Education and Environmental Control</b> <ul style="list-style-type: none"><li>SABA as needed for symptoms. Intensity of treatment depends on severity of symptoms.</li><li>With viral respiratory symptoms: SABA q 4–6 hours up 24 hours (longer with physician consult). Consider short course of oral systemic corticosteroids if exacerbation is severe or patient has history of previous severe exacerbation</li></ul> Caution: Frequent use of SABA may indicate the need to step up treatment.					

- The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
- If an alternative treatment is used and response is inadequate, discontinue it and use the preferred treatment before stepping up.
- If clear benefit is not observed within 4–6 weeks, and patient's/family's medication technique and adherence are satisfactory, consider adjusting therapy or an alternative diagnosis.
- Studies on children 0–4 years of age are limited. Step 2 preferred therapy is based on Evidence A. All other recommendations are based on expert opinion and extrapolation from studies in older children.
- Clinicians who administer immunotherapy should be prepared and equipped to identify and treat anaphylaxis that may occur.

**Alphabetical listing is used when more than one treatment option is listed within either preferred or alternative therapy.** ICS, inhaled corticosteroid; LABA, inhaled long-acting  $\beta_2$ -agonist; LTRA, leukotriene receptor antagonist; oral corticosteroids, oral systemic corticosteroids; SABA, inhaled short-acting  $\beta_2$ -agonist.

Continued

**Table 218-5** Stepwise Approach for Managing Asthma Long Term in Children, 0–4 Years of Age and 5–11 Years of Age—cont'd**CHILDREN 5–11 YEARS OF AGE**

Step down if possible (and asthma is well controlled at least 3 months)		Assess control		Step up if needed (first check inhaler technique, adherence, environmental control, and comorbid conditions)			
Intermittent Asthma		Persistent Asthma: Daily Medication					
		Consult with asthma specialist if step 3 care or higher is required. Consider consultation at step 2.					
	STEP 1	STEP 2	STEP 3	STEP 4	STEP 5	STEP 6	
Preferred	SABA PRN	Low-dose ICS	Low-dose ICS + LABA, LTRA, or Theophylline	Medium-dose ICS + LABA or Montelukast	High-dose ICS + LABA	High-dose ICS + LABA + Oral corticosteroids	
Alternative		Cromolyn, LTRA, Nedocromil, or Theophylline	OR Medium-dose ICS	Medium-dose ICS + LTRA, or Theophylline	High-dose ICS + LTRA, or Theophylline	High-dose ICS + LTRA, or Theophylline + Oral corticosteroids	
Quick-Relief Medication	<b>Each Step: Patient Education, Environmental Control, and Management of Comorbidities</b> Steps 2–4: Consider subcutaneous allergen immunotherapy for patients who have persistent, allergic asthma. <ul style="list-style-type: none"><li>SABA as needed for symptoms. Intensity of treatment depends on severity of symptoms: up to 3 treatments at 20-minute intervals as needed. Short course of oral systemic corticosteroids may be needed</li></ul> Caution: Increasing use of SABA or use >2 days a week for symptoms relief (not prevention of EIB) generally indicates inadequate control and the need to step up treatment.						

- The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
- If an alternative treatment is used and response is inadequate, discontinue it and use the preferred treatment before stepping up.
- Theophylline is a less desirable alternative due to the need to monitor serum concentration levels.
- Steps 1 and 2 medications are based on Evidence A. Step 3 ICS and ICS plus adjunctive therapy are based on Evidence B for efficacy of each treatment and extrapolation from comparator trials in older children and adults—comparator trials are not available for this age group; steps 4–6 are based on expert opinion and extrapolation from studies in older children and adults.
- Immunotherapy for steps 2–4 is based on evidence B for house-dust mites, animal danders, and pollens; evidence is weak or lacking for molds and cockroaches. Evidence is strongest for immunotherapy with single allergens. The role of allergy in asthma is greater in children than adults.
- Clinicians who administer immunotherapy should be prepared and equipped to identify and treat anaphylaxis that may occur.

**Alphabetical listing is used when more than one treatment option is listed within either preferred or alternative therapy.** ICS, inhaled corticosteroid; LABA, inhaled long-acting  $\beta_2$ -agonist; LTRA, leukotriene receptor antagonist; SABA, inhaled short-acting  $\beta_2$ -agonist.

### Quick-Relief Medications

Short-acting inhaled  $\beta_2$ -agonists are the most widely used quick-relief medications because of their rapid onset of action (within minutes) and effectiveness in reversing bronchospasm. They promote smooth muscle relaxation, decrease vascular permeability, and enhance mucociliary clearance. Notably, the long-acting  $\beta$ -agonists, such as salmeterol and formoterol, are not currently recommended for use as quick-relief inhalers because the FDA expressed concerns about increasing the risk for severe asthma exacerbations.  $\beta_2$ -Agonists also can limit exercise-induced bronchospasm. Side effects include tachycardia, tremor, headaches, and palpitations. Levalbuterol, the racemic R isomer, has been observed by some investigators to have fewer systemic effects for the same degree of bronchodilation than albuterol, with others reporting negligible clinical effect. These symptoms can be

reduced by use of selective  $\beta$ -agonist medications such as those listed previously and spacer/holding chambers. Metabolic abnormalities, such as hypokalemia and hyperglycemia, have been reported with frequent or continuous use of  $\beta$ -agonists, although the clinical significance of these findings is unclear. Excessive reliance on quick relievers has been associated with increased risk for death or worsening asthma. Use of more than 1 canister per month is associated with poorly controlled asthma and risk for exacerbations, whereas use of more than 2 canisters of albuterol per month is associated with risk for fatal asthma exacerbations. It is important to remember that most canisters have 200 inhalations in each unit (100 doses of 2 puffs each); hence close monitoring of SABA use may help detect children unable to recognize inadequate asthma control. It is also important that children keep close track of the number of

inhalations used per canister, particularly for inhalers that do not have a counter built in.

Anticholinergic agents in combination with albuterol have been shown to have a positive effect on reducing the rate of hospitalizations during acute asthma exacerbations, although, singly, they are less potent than SABAs. The most common anticholinergic agent in use is ipratropium bromide because it is available in both MDI and nebulized forms and has limited central nervous system side effects. This agent decreases vagal tone (resulting in bronchodilation) and blocks reflex bronchoconstriction to irritants.

Oral short courses of corticosteroids are used to treat asthma exacerbations and may be considered quick-relief medications. These drugs have broad anti-inflammatory effects and are usually used as a short 3- to 5-day course to gain initial control of asthma and to speed resolution of moderate or severe persistent exacerbation. The available preparations—prednisone, prednisolone, and methylprednisolone—are rapidly and completely absorbed, with peak plasma concentrations occurring within 1 to 2 hours. They are typically administered in a dose of 1 to 2 mg/kg/day. Requirement of less than 2 corticosteroid courses per year is one of the criteria indicating well-controlled asthma. Recently the use of 1 to 2 doses of dexamethasone in the ED setting as equivalent therapy to prednisone/prednisolone for acute asthma exacerbations in pediatric patients was explored. Although there was no significant difference in relative risk for relapse, the palatability and the large quantity of the liquid dexamethasone preparation that needs to be ingested may be a limitation to its widespread use among children.

### Long-Term Controller Medications

As discussed earlier, children identified as having persistent asthma should be prescribed daily controller medications. The types of controller medications are ICS, LABAs, ICS-LABA combinations, leukotriene modifiers, sustained-release theophylline, mast cell stabilizers (cromolyn and nedocromil), omalizumab, and low-dose corticosteroid therapy.

Inhaled corticosteroids are recommended as the first-line treatment for most types of persistent asthma. These drugs bind to the glucocorticoid receptors in cytoplasm and translocate into the nucleus, where they regulate transcription of target genes, leading to inhibition of inflammatory cytokines and upregulation of  $\beta_2$ -receptor responsiveness. They block late-phase reaction to allergens, reduce airway hyperresponsiveness, and are the most potent and effective anti-inflammatory medications currently available. They lessen asthma symptoms, improve pulmonary function, reduce the need for quick-relief medications, and halve the amount of urgent care visits, systemic corticosteroid use, and hospitalizations for acute asthma exacerbations.

There are different formulations of ICS approved by the FDA for use in children, available in different preparations—as an MDI, dry powder inhaler, or nebulizer solution. Direct comparisons of efficacy and safety in children are limited and, notably, approval age varies with each preparation.

In general, ICS are well tolerated and safe at the recommended dosages. The dose-response curve for ICS treatment begins to flatten for many measures of efficacy at low to medium doses. Most benefit is achieved with relatively low doses, whereas the risk for adverse effects increases with higher doses. The major concern with long-term use of ICS is growth delay, with a recent study suggesting a decrease in height of up to half an inch. Other potential side effects of long-term ICS use include osteoporosis and, in the older population, ocular problems such as cataracts and glaucoma. The most common side effect is oral candidiasis. The choice of ICS preparation prescribed depends on the relative potential for adverse effects and the desired level of symptom control in individual children. Issues to consider include the drug delivery device, dose level, formulation of the preparation, bioavailability, potency of the inhaled corticosteroid, and deposition either in the pulmonary system or in the gastrointestinal system. Strategies to minimize side effects include using the lowest dose needed to control asthma, using less bioavailable formulations, using spacers or holding chambers with MDI, rinsing the mouth after inhalation, adding LABA to a low-medium dose of ICS rather than increasing ICS, monitoring growth, and ensuring age-appropriate dietary intake of calcium and exercise. It should be noted that children may relapse when inhaled corticosteroids are reduced or discontinued; hence, regular monitoring is recommended.

Leukotriene modifiers include inhibitors of leukotriene synthesis such as 5-lipoxygenase inhibitors (zileuton) and LTRAs, such as montelukast and zafirlukast, that block LTD<sub>4</sub> receptors. These medications are popular because they can be administered in oral form and have been shown to have bronchodilator and anti-inflammatory properties and mitigate exercise-, allergen-, and aspirin-induced bronchospasm. Only montelukast (>6 months of age) and zafirlukast (>5 years of age) are FDA approved for children. As single agents, they are considered “alternate” therapy in mild persistent asthma. They can also be used with inhaled corticosteroids. The medications may have some drawbacks, particularly because they can, in some cases, affect the pharmacokinetics of certain medications (eg, zafirlukast affects warfarin). Rare cases of Churg-Strauss syndrome have been reported in adults with corticosteroid-dependent asthma treated with LTRA, although it is not clear if they merely “unmasked” underlying disease or caused it. Recent post-marketing reports have raised awareness about potential for neuropsychiatric and behavioral effects of montelukast ranging from headaches and agitation to nightmares, oppositional behavior, anxiety and depression, and even suicidal thinking and behavior.

Long-acting  $\beta_2$ -agonists, such as salmeterol and formoterol, are not intended for treating acute exacerbations or as monotherapy for persistent asthma. These medications have long lipophilic side chains and anchor them to the cell membrane, allowing them to interact repetitively with  $\beta$ -receptors, thereby increasing the duration of action for up to 12 hours. These medications act by relaxing bronchial smooth muscle, improving symptoms, and reducing the need for quick-relief

medication. Formoterol has a quick onset of action, similar to SABA, whereas salmeterol has a longer onset of action. Fixed-dose combination therapy of ICS-LABA (fluticasone/salmeterol, budesonide/formoterol, mometasone/formoterol) is available and is recommended over using separate inhalers. Their major indication is as an add-on agent when asthma is uncontrolled by ICS therapy alone. In those children, the ICS-LABA combination therapy has been shown to be synergistic and superior to increasing ICS dose, both in terms of efficacy and minimizing steroid-induced side effects. Notably, the FDA requires all LABA-containing medications to carry a black box warning regarding potential for worsening asthma while on therapy. The FDA also specifies that LABAs should be discontinued when asthma control is achieved, and asthma should be maintained with controllers such as ICS.

Cromolyn sodium and nedocromil sodium are mast cell stabilizers that can attenuate the early- and late-phase response after allergen challenge. They are considered alternate anti-inflammatory agents for children with mild persistent asthma. Although they have good safety profiles, they need to be administered frequently (4 times a day) and are not as efficacious as ICS or leukotriene antagonists. Cromolyn is dispensed in a nebulizer solution or as an MDI. Nedocromil is also available as an MDI, although it has not been in favor in recent years because of its unpleasant taste. Both nedocromil and cromolyn may be used as an adjunct to pretreatment with SABA for exercise-induced bronchospasm. Although these medications are listed in the NHLBI guidelines document, it should be noted that they are not regularly used and may be difficult to find in pharmacies.

Theophylline (methylxanthine), a phosphodiesterase inhibitor, has anti-inflammatory effects in addition to bronchodilatory properties, although its role has diminished in the treatment of children with asthma. Although methylxanthines can reduce asthma symptoms and are considered alternate agents for older children with mild persistent asthma, they are a challenge to use because of their narrow therapeutic window and require frequent monitoring. In addition, their use is limited by numerous side effects, such as headaches and vomiting, including some that are life-threatening, such as cardiac arrhythmias, seizures, and death. Theophylline metabolism and serum levels are altered by fever, viral illnesses, certain drugs such as cimetidine and erythromycin, and liver disease. They are, therefore, generally not used for mild persistent asthma. Theophylline may rarely be considered for use in recalcitrant severe asthma by some asthma specialists, particularly for reduction of nocturnal symptoms. Suggested target peak levels are now 5 to 10 mcg/dL as opposed to the higher levels (10–20 mcg/dL) that were previously used; serious adverse effects are much less common with this dosing strategy.

Omalizumab is an anti-IgE humanized monoclonal antibody that binds circulating IgE, thereby binding the high-affinity receptor and preventing IgE-mediated allergic responses and inflammatory cascade. It does not activate complement or bind to IgE attached to mast cells. When bound, it forms small biologically inert anti-IgE complexes and decreases circulating

serum IgE levels. Studies have shown that serum IgE levels directly correlate with the odds ratio for the development of asthma. In addition, total serum IgE has been shown to be directly related to asthma and wheezing in the first 5 years of life. Omalizumab has been shown to improve lung function, to significantly reduce sputum eosinophil counts, and to improve quality of life. It is FDA approved for children 12 years of age and older with moderate to severe asthma, documented hypersensitivity to a perennial aeroallergen, and inadequate disease control with ICS or oral corticosteroids. Hypersensitivity reactions (including anaphylaxis) have been variably reported, and the FDA has mandated a black box warning of potentially serious anaphylactic reactions with its use. Although initial concerns about increased risk for malignancies is now mitigated, the FDA announced a new safety communication describing an increased risk for cardiac and brain adverse events, particularly in adults, and there is a question of cardiac effects in adults. Currently, it is used only by asthma specialists, is administered every 2 to 4 weeks subcutaneously, and dose depends on the child's weight and serum IgE level.

## APPROACH TO DIFFICULT-TO-MANAGE DISEASE

Five issues should be assessed when dealing with a child who does not respond to reasonable therapy.

1. Is it asthma? Anatomic lesions or other medical conditions should be ruled out.
2. Is the child adherent to the medication regimen, and is her technique for the medication delivery appropriate?
3. Did the child run out of medication and not realize it or say so?
4. Is a continual exposure present, environmental or otherwise, that is continuing to cause problems for the child?
5. A referral or a second opinion from a specialist should be considered if the desired effect is not being achieved.

## WHEN TO REFER

- A child older than 5 years of age requires step 4 care or higher, or a child younger than 5 years of age requires step 3 care or higher.
- A child has life-threatening asthma exacerbation or intensive care admission.
- Goals of therapy are not met after 3 to 6 months of treatment.
- Diagnosis or management is complicated by comorbid conditions (eg, sinusitis, nasal polyps, severe rhinitis, uncontrolled gastroesophageal reflux, and vocal cord dysfunction).
- Additional diagnostic tests are needed (eg, allergy skin testing, bronchoscopy).
- Allergen immunotherapy is a consideration.
- The asthma is difficult to control.
- Occupational triggers are suspected.
- Psychological or psychiatric issues are suspected.

### WHEN TO ADMIT

- Children who are moderately to severely ill on arrival and do not respond to  $\beta$ -agonist rescue therapy
- Continued symptoms despite treatment
- Significant wheezing and retracting (hunched posture, chest and neck pulling in), trouble speaking, gray or blue lips or fingernails
- Altered mental status, such as drowsiness or agitation
- Peak flows less than 50% of personal best
- Requiring  $\beta$ -agonists every 2 to 3 hours
- Continued need for supplemental oxygen despite initial therapy

Additional factors that may influence the decision about hospitalization include

- Use of  $\beta_2$ -agonists/glucocorticoids before ED visit
- History of poor adherence to the medical regimen
- Caretaker inability to provide careful medical care and supervision at home
- Inadequate access to medical care
- History of rapid progression of severity in past exacerbations

### TOOLS FOR PRACTICE

#### Community Coordination and Advocacy

## Chapter 219 ATOPIC DERMATITIS

Linda S. Nield, MD; Jonette E. Keri, MD, PhD

### DEFINITION

Atopic dermatitis (AD) is a multifactorial dermatologic condition involving chronically relapsing inflammation of the skin. It is sometimes referred to as eczema, which is a general term used to describe skin that is

erythematous, scaling, vesicular, and crusting. AD is common in individuals with the genetic propensity to develop immunoglobulin E (IgE)-mediated diseases. The associated IgE-mediated diseases include allergic rhinitis, asthma, and food allergies. AD may be the initial condition signaling the progression to further allergic diseases, known as the atopic march.

## ETIOLOGY

The exact cause of AD is unknown, but genetic and environmental factors play a role in its development. Dysfunction of the immune system, specifically abnormal IgE-mediated type I and cell-mediated type IV reactions, and dysfunction of the epidermal barrier occur. Filaggrin is a structural protein in the stratum corneum, and mutations in the filaggrin gene (*FLG*) have been reported to have a key role in the pathogenesis of AD. Loss of function mutations in *FLG* lead to increased transepidermal water loss and increased entry of allergens and microbes. The T cells responsible for atopy are mainly  $T_H2$  subtype cells. An area of debate is the hygiene hypothesis, which theorizes that decreased exposure to microbes, immunizations, the use of antibiotics, and environmental exposures in early childhood stunts immunologic maturation of  $T_H1$  subtype cells, thereby increasing the risk for development of atopic disease later in life caused by an imbalance in  $T_H2$  and  $T_H1$ , with overexpression of  $T_H2$  responses compared with  $T_H1$  responses.

Other cells implicated in the development of AD include macrophages, IgE-bearing Langerhans cells, eosinophils, and mast cells, which release or produce several proinflammatory agents such as histamine, leukotrienes, and prostaglandins. The resulting inflammatory reactions lead to disruption of the epidermis.

Airborne allergens (dust mites, cat and dog dander, molds, pollen), foods (especially milk, eggs, and peanuts), infectious agents, and other contact allergens have been implicated as potential antigenic triggers. Psychological stress may exacerbate AD.

## EPIDEMIOLOGIC FEATURES

Atopic dermatitis is predominantly a disease of infancy and childhood. Onset occurs in the first year of life in most affected individuals. The prevalence of disease varies depending on age; more than 10% of infants and young children may be affected, whereas one-half this rate occurs in adolescents. DaVeiga reports a remission rate of 60% in a review about AD in children and adults. A survey in 2007 found that almost 18 million Americans had a self-reported diagnosis of AD, and more than one-third of them had diagnosis confirmed by a physician. Both sexes are affected equally. The yearly health care cost of AD in the United States has been projected to be as high as almost \$4 billion.

## DIAGNOSIS

The diagnosis of AD is determined solely by history and clinical examination. The criteria for diagnosis of AD were defined by Hanifin and Lobitz. These criteria

### BOX 219-1 Clinical Criteria of Atopic Dermatitis

- A. Essential features (must be present) of atopic dermatitis (AD)
  1. Pruritus
  2. Eczema (acute, subacute, chronic)
    - a. Typical morphology and age-specific patterns<sup>a</sup>
    - b. Chronic or relapsing history
- B. Important features (seen in most cases, adding support to the diagnosis)
  1. Early age at onset
  2. Atopy
    - a. Personal and/or family history
    - b. IgE reactivity
  3. Xerosis
- C. Associated features (these clinical associations help to suggest the diagnosis of AD but are too nonspecific to be used for defining or detecting AD for research or epidemiologic studies)
  1. Atypical vascular responses (eg, facial pallor, white dermographism, delayed blanch response)
  2. Keratosis pilaris/hyperlinear palms/ichthyosis
  3. Ocular/periorbital changes
  4. Other regional findings (eg, perioral changes/periauricular lesions)
  5. Perifollicular accentuation/lichenification/prurigo lesions

*Exclusionary conditions:* It should be noted that a diagnosis of AD depends on excluding conditions such as scabies, seborrheic dermatitis, allergic or irritant contact dermatitis, ichthyoses, cutaneous lymphoma, psoriasis, and immune deficiency diseases.

<sup>a</sup>Patterns include: (1) facial, neck, and extensor involvement in infants and children; (2) current or prior flexural lesions in any age group; (3) sparing of groin and axillary regions  
From Eichenfield LF, Hanifin JM, Luger TA, Stevens SR, Pride HB. Consensus conference on pediatric atopic dermatitis. *J Am Acad Dermatol.* 2003;49: 1088–1095, with permission from Elsevier.

are presented in Box 219-1 and are useful in identifying characteristics of patients who have AD. However, patients may have AD and not meet the criteria as originally defined.

## DIFFERENTIAL DIAGNOSIS

Differentiating AD from other skin conditions may be difficult in some instances, but certain characteristics will aid in the diagnosis (Box 219-2). Seborrhea is associated with scaling, commonly on the scalp, forehead, and around the eyebrows; it can also be accompanied by pruritus. The diagnosis of contact dermatitis often requires a positive exposure history to a potential offending agent and will be limited in distribution on the body to the area of contact. Contact dermatitis is more likely to have an acute onset and localized appearance. Absence of a family history also favors a diagnosis of seborrhea or contact dermatitis.

**BOX 219-2 Differential Diagnosis for Atopic Dermatitis**

- Seborrheic dermatitis
- Contact dermatitis (allergic and irritant)
- Psoriasis
- Scabies
- Dermatophyte infection
- Wiskott-Aldrich syndrome
- Leiner disease
- Histiocytosis X
- Ataxia
- Telangiectasia
- Ahistidinemia
- Severe combined immunodeficiency
- Eosinophilic esophagitis
- Acrodermatitis enteropathica (zinc deficiency)
- Niacin deficiency
- Phenylketonuria

**CLINICAL MANIFESTATIONS**

Atopic dermatitis may exhibit as an acute dermatitis associated with severe pruritus, redness, vesicles, and exudation, or it may have a subacute pattern of pruritus, redness, and scaling. Chronic lesions are marked by excoriations, lichenification (thickened skin and deeper or exaggerated skin lines), and postinflammatory hypopigmentation or hyperpigmentation.

AD has three distinct stages: infantile, childhood, and adult. In infants, AD is characterized by an eruption of erythematous papules on facial cheeks and extensor surfaces of arms and legs. The hair is dry, and the scalp is often scaly. The childhood stage begins at approximately age 3 and lasts through puberty. The areas most affected include the antecubital and popliteal folds, neck, and flexor surfaces of wrists and ankles. Clinically, patients in this stage display a more subacute and chronic dermatitis. The adult stage, beginning at puberty onward, is an extension of the childhood stage. Additional clinical signs include diffuse involvement of the body, with xerosis, lichenification, and central facial pallor.

Other associated clinical manifestations include keratosis pilaris, lichen spinulosus, pityriasis alba, Dennie-Morgan folds, urticaria, hyperlinear palms, juvenile plantar dermatosis, nummular eczema, and cataracts (anterior subcapsular, to distinguish from those secondary to corticosteroids). Keratosis pilaris is a disorder of hyperkeratosis. Its characteristic goose-flesh appearance is secondary to multiple, small, skin-colored or mildly erythematous keratotic papules located on the upper arms, thighs, and facial cheeks. Lichen spinulosus also involves hyperkeratosis; in this condition, tiny hairlike spines top the small papules that occur in crops on various locations on the body. Juvenile plantar dermatosis mainly affects the feet, rarely the hands, and produces shiny, fissured skin on the plantar surfaces.

**LABORATORY EVALUATIONS**

No routine laboratory studies are needed to diagnose AD. Specific tests to rule out the disorders in the differential list may be necessary on a case-by-case basis if the diagnosis is in question. For example, if recurrent infections occur in the patient, then an immunodeficiency workup should be considered. Bacterial cultures of encrusted or exudative skin lesions and nares to detect colonization with staphylococcal organisms are warranted in any patient in whom secondary infection is suspected and improvement is not noted with standard therapy. Patch testing may be considered to pinpoint potential antigenic triggers, which may add a component of contact dermatitis to the existing AD. Skin biopsy may be necessary when definitive diagnosis is in question.

**MANAGEMENT****Uncomplicated Case**

Treatment of AD is directed at relieving dryness, inflammation, and pruritus and eradicating secondary bacterial infections. Daily applications of emollients, especially after brief warm baths, in the form of creams or ointments are the most efficacious way of treating dryness. Ointments are better in more severe cases and are better than creams. However, if discomfort (ie, stinging sensation) occurs with ointment application, or if the ointment feels too occlusive, such as in humid warm weather, then creams can be substituted. Bathing should last no longer than 5 minutes, and mild soaps or nondetergent cleansers are recommended to wash the body. The patient should be patted dry with a towel, the emollient applied immediately to all skin, and the prescription topically applied to affected areas.

Inflammation is best treated with topical corticosteroids. Generally, ointments tend to work better than creams. However, creams are sometimes preferred for cosmetic appeal and can be used for acute weeping, erythematous lesions. Ointments remain the choice for chronic dermatitis in which dryness and lichenification predominate. A low-potency topical steroid such as 1% to 2.5% hydrocortisone or desonide can be used for mild disease even on the diaper area and face; twice-daily dosing should be limited to a 2-week course or less. Mid- to high-potency steroids, such as triamcinolone or fluocinonide, can be used in more severe cases of AD on the trunk and extremities. Strong, halogenated steroids should not be applied to the face, axillae, or groin, and an oral systemic steroid should rarely be prescribed. The adverse effects of topical steroids increase with increasing potency. The most worrisome side effects include dermal and epidermal atrophy and suppression of the pituitary-adrenal axis. Applying topical steroids to the occluded groin area of a diapered child increases the risk for systemic side effects.

Topical tacrolimus and pimecrolimus are relatively new anti-inflammatory agents approved for children aged two years and older. Most efficacious in mild to moderate disease, these nonsteroidal immunomodulators are calcineurin inhibitors and alternatives to topical steroids that can be applied to the face. The US

Food and Drug Administration has added a black-box warning to tacrolimus ointment and pimecrolimus cream based on a theoretical risk for malignancy derived from safety profiles of oral calcineurin inhibitors. In general, these topical medications are considered safe and effective. Other medications for AD, such as coal tar (can be useful for scalp, ie, in shampoos) and doxepin (a tricyclic antidepressant with antihistaminic properties), are not routinely prescribed by pediatricians. In recent years, more attention has been placed on the development of barrier-repair creams to help patients with AD. These medications represent a steroid-sparing option.

Although evidence is lacking that antihistamines help relieve the pruritus associated with AD, they are often prescribed, especially for patients with accompanying allergic rhinitis, urticaria, and sleep disturbance. Non-sedating antihistamines such as loratadine can be used daily. The sedating antihistamines, hydroxyzine and diphenhydramine, are most useful at bedtime. Behavior modification such as teaching the child to rub rather than scratch and wearing mittens or socks on the hands to bed at night will help lessen the itch-scratch cycle. Frequent trimming of the child's fingernails may decrease the amount of trauma applied to skin and reduce secondary infection.

The role of dietary management of patients with AD remains controversial. Dietary changes should be judicious. Peanuts, milk, and eggs are the most common food culprits. If food allergies are highly likely as determined by a pediatric allergist, then strict avoidance of foods that serve as antigenic triggers should be encouraged, remembering that more than 90% of IgE-mediated food allergies in children are caused by 8 foods: cow milk, hen eggs, soy, peanuts, tree nuts (and seeds), wheat, fish, and shellfish. Children with documented food allergies should avoid ingesting the involved foods and antigens, receive nutritional counseling and education about reading nutrition labels, and have growth closely monitored. The efficacy of alternative medicine treatments for food allergies, such as herbal or probiotic supplementation, remains unclear, and clinical trials have varying results.

### Complicated Case

If AD continues to flare despite adherence with medication and appropriate skin care, then secondary infection may be responsible. Many patients who have AD have significant colonization with *Staphylococcus aureus*. Along with susceptibility to recurrent bacterial infection, the patient with AD is also prone to herpes simplex virus, human papillomavirus (HPV), and molluscum contagiosum. Secondary bacterial infections usually respond well to topical or oral antibiotics. Cephalexin, dicloxacillin, amoxicillin-clavulanate, azithromycin, and clindamycin are reasonable choices for oral treatment, and mupirocin is the topical antibiotic of choice. Dilute bleach baths (along with intranasal mupirocin) have been reported to improve outcomes (decreased severity of AD) when patients had signs of secondary bacterial infections. If recalcitrant *S aureus* superinfection occurs, then hospitalization for aggressive care and intravenous antibiotics may be required. Cultures of the skin may help identify

appropriate antibiotic sensitivities. Application of nasal mupirocin may be necessary to eradicate bacterial carriage. A widespread herpes infection, known as eczema herpeticum or Kaposi varicelliform eruption, will require treatment with intravenous acyclovir. Various treatment modalities are available for HPV and molluscum contagiosum infection in the patient with AD, who is likely to have a more severe, persistent course of these usually self-limited conditions. HPV treatments include vesicants, immunomodulators, cryotherapy, or ablation with carbon dioxide laser. Molluscum contagiosum can be treated with manual expression, cryotherapy, or topical application of cantharidin or imiquimod.

More aggressive interventions such as systemic immunomodulators or ultraviolet light therapy for severe cases would be prescribed at the discretion of the skin experts.

## PREVENTION

Atopic dermatitis cannot be cured, but meticulous adherence to proper skin care can control symptoms and secondary infection. Moisturization of the skin with daily applications of emollients, especially after bathing, is crucial to keep the skin hydrated. Prevention or delay of onset of AD may be possible with the use of hydrolyzed formula in the first 4 to 6 months of life for infants who are not exclusively breastfed. Extensively hydrolyzed formulas likely have an advantage over partially hydrolyzed formulas. Although some reports suggest that breastfeeding increases the risk for AD, evidence exists supporting breastfeeding as means of reducing the risk for AD.

### WHEN TO REFER

- Recalcitrant cases to dermatologist or an allergist
- To dermatologist for aggressive treatment of secondary HPV or molluscum contagiosum infection

### WHEN TO ADMIT

- Severe cases requiring systemic immunomodulation
- Extensive secondary bacterial infection requiring intravenous antibiotics
- A widespread herpes infection (eczema herpeticum, Kaposi varicelliform eruption)

**Chapter 220****ATTENTION-DEFICIT/  
HYPERACTIVITY DISORDER**

Laurel K. Leslie, MD, MPH; James Guevara, MD, MPH

**CASE REPORT**

Bethany, a 12-year-old girl, arrives for her first visit at your office with her aunt, Cassandra. Cassandra is Bethany's legal guardian and is concerned that Bethany is failing school. Cassandra, who has raised Bethany from birth, tells you that Bethany was born 2 months early to a mother who abused drugs and alcohol during pregnancy. Although Bethany was a colicky infant who was difficult to feed, she had no major problems after birth and has been healthy except for a few early ear infections. She has since developed into a very social child with endless energy and is currently active with cheerleading. Bethany's talkativeness appeared in preschool and has been noted by every teacher since then. At age 6, she was unable to read simple words but was reported to have made "adequate" progress on reading through elementary school. Although Bethany has never received evaluations or services through school, Cassandra has been helping significantly by structuring Bethany's approach to her schoolwork and by paying for private tutoring. Bethany is a slow reader, has been very unhappy about her academic performance, is having trouble falling asleep, and is difficult to arouse in the morning. Her appetite has been poor, although she insists that she is just not hungry. She denies any suicidal thoughts. Her grades had been average until last year, when she began middle school and started failing. On

physical examination, Bethany is at the 75<sup>th</sup> percentile for height, weight, and head circumference. Her vital signs, vision screening, and hearing screening are normal. She has no dysmorphic features and her physical examination is normal. Bethany is articulate and answers your questions willingly.

**DEFINITION OF TERMS**

Bethany illustrates a frequently occurring presentation to pediatric primary care offices—the child or adolescent with school problems of unclear cause. Attention-deficit/hyperactivity disorder (ADHD), one of the most common neurodevelopmental disorders in children and adolescents, is often diagnosed in children with academic achievement or behavioral problems in primary care settings.

According to the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-5), the hallmarks of this disorder are hyperactivity, impulsivity, and inattention that are inconsistent with developmental level and directly affect social and academic/occupational activities. The criteria, as depicted in Box 220-1, require that a child meet a minimum of 6 of 9 inattention criteria or 6 of 9 hyperactivity or impulsivity criteria for at least 6 months duration (this requirement drops to 5 of 9 criteria for adolescents ages ≥17). Furthermore, the criteria stipulate that symptoms must be present before age 12 years; occur in 2 or more settings (eg, home and school); interfere with or reduce the quality of social, academic, or occupational functioning; not occur exclusively during the course of schizophrenia or another psychotic disorder; and not be better accounted for by another mental disorder. The current diagnostic criteria do not account for differences in presentation by age, gender, race, or ethnicity. Therefore, physicians will need to exercise judgment in their use of the criteria.

**PREVALENCE**

A review of community-based epidemiologic studies has estimated the prevalence of ADHD at 6.8% of school-aged children. Boys are diagnosed at a rate 3 times that of females (9.2% vs. 3.0%). The rates of diagnosed ADHD increase with age up to 9 years of age and level off or decline depending on whether children are taking medications. Differences exist in diagnosed prevalence by race or ethnicity; white children are diagnosed at a greater rate (8.6% vs. 7.7% and 3.7%) than black or Hispanic children.

**CLINICAL MANIFESTATIONS**

The core symptoms associated with ADHD interfere with attainment of many of the normal developmental milestones of childhood and adolescence, such as academic, fine motor, social, and adaptive skills. Children identified with ADHD and monitored into adolescence demonstrate an increased risk for poor academic attainment, impaired familial and peer functioning, lower self-esteem, substance abuse, delinquency, and driving-related accidents. Some evidence suggests that treatment may ameliorate some of this risk, particularly for substance abuse. Although many children with ADHD continue to experience symptoms

**BOX 220-1 DSM-5 Criteria for ADHD**

A. A persistent pattern of inattention and/or hyperactivity-impulsivity that interferes with functioning or development, as characterized by (1) and/or (2):

1. Inattention: Six (or more) of the following symptoms have persisted for at least 6 months to a degree that is inconsistent with developmental level and that negatively impacts directly on social and academic/occupational activities:

NOTE: The symptoms are not solely a manifestation of oppositional behavior, defiance, hostility, or failure to understand tasks or instructions. For older adolescents and adults (age 17 and older), at least 5 symptoms are required.

- a. Often fails to give close attention to details or makes careless mistakes in schoolwork, at work, or during other activities (eg, overlooks or misses details, work is inaccurate).
- b. Often has difficulty sustaining attention in tasks or play activities (eg, has difficulty remaining focused during lectures, conversations, or lengthy reading).
- c. Often does not seem to listen when spoken to directly (eg, mind seems elsewhere, even in the absence of obvious distraction).
- d. Often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace (eg, starts tasks but quickly loses focus and is easily sidetracked).
- e. Often has difficulty organizing tasks and activities (eg, difficulty managing sequential tasks; difficulty keeping materials and belongings in order; messy, disorganized work; has poor time management; fails to meet deadlines).
- f. Often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort (eg, schoolwork or homework; for older adolescents and adults, preparing reports, completing forms, reviewing lengthy papers).
- g. Often loses things necessary for tasks or activities (eg, school materials, pencils, books, tools, wallets, keys, paperwork, eyeglasses, mobile telephones).
- h. Is often easily distracted by extraneous stimuli (for older adolescents and adults, may include unrelated thoughts).
- i. Is often forgetful in daily activities (eg, doing chores, running errands; for older adolescents and adults, returning calls, paying bills, keeping appointments).

2. Hyperactivity and Impulsivity: Six (or more) of the following symptoms have persisted for at least 6 months to a degree that is inconsistent with developmental level and that negatively impacts directly on social and academic/occupational activities:

NOTE: The symptoms are not solely a manifestation of oppositional behavior, defiance, hostility, or failure to understand tasks or instructions. For older adolescents and adults (age 17 and older), at least 5 symptoms are required.

- a. Often fidgets with or taps hands or feet or squirms in seat.
  - b. Often leaves seat in situations when remaining seated is expected (eg, leaves his or her place in the classroom, in the office or other workplace, or in other situations that require remaining in place).
  - c. Often runs about or climbs in situations where it is inappropriate. (Note: In adolescents or adults, may be limited to feeling restless.)
  - d. Often is unable to play or engage in leisure activities quietly.
  - e. Is often “on the go,” acting as if “driven by a motor” (eg, is unable to be or uncomfortable being still for extended time, as in restaurants, meetings; may be experienced by others as being restless or difficult to keep up with).
  - f. Often talks excessively.
  - g. Often blurts out an answer before a question has been completed (eg, completes other people’s sentences; cannot wait for turn in conversation).
  - h. Often has difficulty waiting his or her turn (eg, while waiting in line).
  - i. Often interrupts or intrudes on others (eg, butts into conversations, games, or activities; may start using other people’s things without asking or receiving permission; for adolescents and adults, may intrude into or take over what others are doing).
- B. Several inattentive or hyperactive-impulsive symptoms were present prior to age 12 years.
- C. Several inattentive or hyperactive-impulsive symptoms are present in 2 or more settings, (eg, at home, school or work; with friends or relatives; in other activities).
- D. There is clear evidence that the symptoms interfere with, or reduce the quality of, social, academic, or occupational functioning.
- E. The symptoms do not occur exclusively during the course of schizophrenia or another psychotic disorder, and are not better explained by another mental disorder (eg, mood disorder, anxiety disorder, dissociative disorder, personality disorder, substance intoxication or withdrawal).

*Combined presentation:* If both Criterion A1 (inattention) and Criterion A2 (hyperactivity-impulsivity) are met for the past 6 months.

*Predominantly inattentive presentation:* If Criterion A1 (inattention) is met but Criterion A2 (hyperactivity-impulsivity) is not met for the past 6 months.

*Predominantly hyperactive-impulsive presentation:* If Criterion A2 (hyperactivity-impulsivity) is met and Criterion A1 (inattention) is not met for the past 6 months.

Because symptoms can change over time, the presentation may change over time as well.

From American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. Arlington, VA: American Psychiatric Association; 2013; 59–60. Reprinted with permission.

into adulthood, an age-dependent decline seems to exist in apparent symptoms as children grow older. Hyperactivity and impulsivity tend to remit at a greater rate than inattention.

## DIAGNOSIS

Although the diagnosis of ADHD can be made reliably in children using a standardized approach, concerns regarding the validity of the diagnosis of ADHD often arise. At present, no biological marker or gold standard diagnostic test exists that can reliably identify those with and without ADHD. Furthermore, whether the symptoms of ADHD represent a unique disorder or merely one end of the continuum of age-appropriate behavior is unclear. Data that support the validity of ADHD as a unique disorder come from multiple sources. First, cohort studies have consistently shown similar long-term outcomes for children identified with ADHD (predictive validity). Second, twin studies have demonstrated higher concordance rates of ADHD among monozygotic twins than among dizygotic twins or related siblings, suggesting a genetic predisposition. Third, genetic studies have shown higher rates of gene alterations involving dopamine neurotransmission in subjects with ADHD. Finally, brain imaging and physiologic studies have shown a greater proportion of abnormalities among persons with ADHD than similar controls without ADHD, which suggests a neurodevelopmental process leading to ADHD.

Diagnosing ADHD is complicated by the fact that presentations of ADHD in clinical practice can vary substantially. The core symptoms of ADHD result in 3 distinct subtypes recognized in the *DSM-5* (see Box 220-1): a predominantly inattentive subtype (ADHD-IA), a hyperactive/impulsive subtype (ADHD-HI), and a subtype that includes a combination of both inattentive and hyperactive/impulsive features (ADHD-CT). Children with ADHD-IA often present with school underachievement and may go unrecognized by parents and teachers. In contrast, children with ADHD-HI or ADHD-CT commonly present with school underachievement, disruptive classroom behavior, and poor relationships with both peers and family members. In addition, many conditions, including autism, can co-exist with ADHD, further adding to variation in presentation.

Despite these complexities, the American Academy of Pediatrics (AAP) recognizes ADHD as a chronic condition and encourages increasing responsibility for the care of children with ADHD in primary care settings. The AAP published revised evidence-based diagnostic and treatment guidelines for use by primary care pediatricians. These guidelines expanded the age range for ADHD from 6 through 12 years to 4 through 18 years, expanded the scope of recommendations to children with hyperactive or impulsive problem behaviors that do not meet diagnostic criteria, and combined diagnostic and treatment recommendations into a single document.

The decision to support the diagnosis and treatment of ADHD in primary care reflects the high prevalence rates of ADHD in the community, families' perception of the approachability of primary care physicians, an

insufficient supply of child mental health professionals, and the fact that more than 50% of children with ADHD currently receive their care in primary care settings. To support physicians in caring for children with ADHD, the AAP developed an online, interactive training program and, with its Quality Improvement Innovation Network (QuIIN), partnered with the National Initiative for Children's Healthcare Quality (NICHQ) to develop a revised toolkit titled *Caring for Children with ADHD: A Resource Toolkit For Clinicians*, 2nd Edition ([www.aap.org/en-us/professional-resources/practice-support/quality-improvement/Quality-Improvement-Innovation-Networks/Pages/Guidelines-and-Tools-to-Improve-Care-for-Children-with-ADHD-Improvement-Project.aspx](http://www.aap.org/en-us/professional-resources/practice-support/quality-improvement/Quality-Improvement-Innovation-Networks/Pages/Guidelines-and-Tools-to-Improve-Care-for-Children-with-ADHD-Improvement-Project.aspx)). In addition, *Bright Futures in Practice: Mental Health* contains a variety of tools for the early identification of childhood behavioral problems ([www.brightfutures.org/mentalhealth](http://www.brightfutures.org/mentalhealth)). This 2-volume set considers the mental health of children in a developmental context, presenting information on early recognition and intervention for specific mental health problems and mental disorders, including ADHD, and provides a hands-on toolkit for health professionals and families for use in screening, care management, and health education of mental health problems in primary care. The AAP Task Force on Mental Health has also produced a number of resources on the management of mental health concerns in primary care that may be helpful ([www.aap.org/en-us/advocacy-and-policy/aap-health-initiatives/Mental-Health/Pages/Key-Resources.aspx](http://www.aap.org/en-us/advocacy-and-policy/aap-health-initiatives/Mental-Health/Pages/Key-Resources.aspx)).

## DIFFERENTIAL DIAGNOSIS

Because no definitive biologic or imaging markers exist for ADHD, a diagnosis of ADHD requires determining whether a child meets the *DSM-5* diagnostic criteria for ADHD (see Box 220-1) and ascertaining whether any other disorders or factors exist that may better explain a child's symptoms and impairment. Many medical, psychosocial, psychiatric, or neurologic conditions may exhibit symptoms similar to those of ADHD (see Box 220-2). These conditions may be the primary cause of the child's behavioral and attention difficulties or may increase a child's level of impairment if co-morbid with ADHD. The primary care physician is responsible for determining if these conditions are present and, if so, whether they are the primary cause of the child's dysfunction or whether they co-exist with ADHD. Determining the cause of a child's difficulties and any conditions that may coexist requires time and effort, but the evaluation can be streamlined through a careful history and thorough physical examination as reviewed here.

Although other professionals may assist in identifying mental health or educational disorders, establishing whether any medical conditions are present is paramount for primary care physicians. For instance, poor visual acuity or hearing loss can contribute to academic difficulties. Obstructive sleep apnea caused by enlarged tonsils or adenoids or both can be associated with daytime somnolence, hyperactivity, and academic problems. Medication side effects may also explain unusual drowsiness and lack of attention in

**BOX 220-2 Conditions That May Mimic or Co-occur With ADHD****DEVELOPMENTAL DIFFERENCES/NORMAL VARIANTS**

*Normal variation; giftedness; sociocultural differences in expectations or parenting*

**MEDICAL CONDITIONS**

*Medication side effects; substances of abuse; hearing impairment; visual impairment; sleep disorders including obstructive sleep apnea and poor sleep hygiene; toxins (eg, chronic lead exposure or acute lead intoxication; chronic iron-deficiency anemia); thyroid disorders; chronic disease complications*

**NEUROLOGIC/DEVELOPMENTAL CONDITIONS**

*Learning disabilities; autism spectrum disorder; tic disorders (Tourette's); communication disorders; processing disorders; intellectual disability; neuro-developmental syndromes (eg, fetal alcohol syndrome, fragile X syndrome); cerebral palsy; seizure disorders (petit mal or developmental delays); sequelae of central nervous system trauma/infection; neurodegenerative disorders; motor coordination disorders*

**PSYCHOSOCIAL/ENVIRONMENTAL PROBLEMS**

*Stress in family situation (marriage, separation/divorce, birth of sibling, death); stress in environment (new home, new school); family dysfunction; parenting dysfunction; neglect or abuse; parental psychopathology; parental substance abuse; inappropriate educational program*

**EMOTIONAL/BEHAVIORAL CONDITIONS**

*Oppositional defiant disorder; conduct disorder; depressive disorders; anxiety disorders; bipolar disorder; obsessive-compulsive disorder; posttraumatic stress disorder; adjustment reaction; schizophrenia*

Conditions that in general occur more commonly are italicized. The prevalence of any of these conditions vary depending on the characteristics of the setting in which a child is being evaluated.

the classroom. Dermatologic findings, such as café au lait spots, may suggest neurofibromatosis or other neurologic disorders associated with learning and behavioral difficulties. A history of 20 to 50 episodes a day of repeated staring pauses lasting several seconds in both the home and the school settings may lead a physician to consider absence seizures.

**COEXISTING CONDITIONS**

Coexisting conditions commonly found in children with ADHD include oppositional defiant disorder, conduct disorder, mood disorders, anxiety disorders, and learning disabilities (see Chapter 302, Oppositional Defiant Disorder; Chapter 139, Disruptive Behavior and Aggression; Chapter 129, Anxiety; Chapter 137, Depression; Chapter 284, Learning Disorders). A recent review of these disorders found high rates of comorbidity with ADHD across multiple studies. Oppositional defiant disorder was the most common, with an average prevalence rate of 35.2%

(range: 27.2%–43.8%). Conduct disorder 25.7% (range: 12.8%–41.3%), anxiety disorders 25.8% (range: 17.6%–35.3%), and depressive disorders 18.2% (range: 11.1%–26.6%) were also common. Rates of coexisting learning disabilities are also high, ranging from 12% to 50%. For many of these disorders, a careful history will provide important clues for further evaluation. For example, a history of speech delay in early childhood, family history of learning disabilities, problems with decoding words in the early elementary school years, or disparate skill acquisition across math, reading, and spelling suggest a learning disability. Psychosocial and environmental factors also are common and essential to consider (see Box 220-2).

**EVALUATION**

The AAP recommends that children who present with inattention, hyperactivity, impulsivity, academic underachievement, or behavior problems should undergo an evaluation for ADHD. The evidence supporting this recommendation is strong and is derived from clinical studies showing a high prevalence of ADHD among school-age children exhibiting developmental and behavioral concerns. In the opening case report, Bethany's talkativeness and high energy level may represent hyperactivity, impulsivity, or both. This situation combined with her history of academic difficulties, particularly on entry to middle school when attention to detail and organizational skills are increasingly necessary, should prompt an evaluation for ADHD and related conditions.

**History**

A comprehensive history with particular attention to the presenting complaint, development, school history, family history, and social history is essential to the evaluation and can help identify other problem areas or provide clues to other diagnoses. Sample comprehensive intake forms are available as part of the revised ADHD toolkit. The physical examination, though usually normal, can help identify other problems that may contribute to or represent the cause of a child's behavior problems. In addition, the history and physical examination may allow the opportunity to determine whether there are any suggestions of medical problems that may explain a child's symptoms and to assess a child's mental status and interaction with caregivers.

**Laboratory and Imaging Studies**

Laboratory or imaging tests are not indicated in the routine assessment of ADHD, but may be appropriate if the review of symptoms or physical examination suggests an alternative diagnosis. For example, plumbism and thyroid dysfunction are often thought to be associated with behavioral problems. However, blood lead levels and thyroid hormone levels are infrequently abnormal in children with ADHD, and little evidence exists that these tests adequately discriminate between children with ADHD and without. Children with ADHD often have abnormalities noted on brain imaging or electroencephalography. However, the abnormalities are not consistent, do not usually

represent clinically significant findings, and do not adequately discriminate between children with and without ADHD. Continuous performance tests are often touted as scientific measures of vigilance and distractibility that can help confirm a diagnosis of ADHD, but systematic reviews of these tests find that their sensitivity and specificity (<70%) are inadequate to reliably distinguish between children with and without ADHD.

### Diagnostic Criteria and Diagnostic Tools

The current AAP guidelines recommend that a child must meet *DSM-5* criteria to receive a diagnosis of ADHD. The AAP supports the use of these criteria to ensure a valid diagnosis is made in primary care and to decrease variation in the diagnostic process among physicians. ADHD-specific behavior rating scales probe for the presence of ADHD diagnostic criteria and other behavioral problems and can be used to ensure uniformity in how diagnostic criteria are met (Table 220-1). In addition, ADHD rating scales provide cut-point scores that, when exceeded, indicate an increased likelihood that ADHD is present. Several excellent ADHD rating scales for parent and teacher respondents are commercially available to physicians (see Tools for Practice), including the Vanderbilt Rating Scales, the ADHD Rating Scale, the Conners' Rating Scales, and the SNAP rating scales. The Vanderbilt Rating Scales are also available in the public domain at no cost. Other more general behavior rating scales, such as the Child Behavior Checklist and the Behavior Assessment System for Children do not

include ADHD diagnostic criteria and lack adequate sensitivity and specificity (approximately 86%) for the diagnosis of ADHD and related disorders. However, they may be used to triage children for specific rating scales or diagnostic interviews or to give a more global impression of a child's functioning. None of these tools alone can determine whether a child has a particular disorder; only a trained clinician should make a diagnosis after a thorough evaluation. Any symptoms suggestive of possible harm to self or others warrant immediate evaluation by a skilled clinician.

In addition to determining whether children meet symptom criteria, clinicians should determine whether children demonstrate poor functioning as a result of symptoms. For example, the Vanderbilt Rating Scales have questions that address academic and social functioning and can be used to assess relative strengths and weaknesses. Clinicians should obtain this information from both parents and teachers. Given that children spend a substantial amount of time in the classroom, the AAP guidelines stipulate that clinicians should obtain data from schools on children's level of functioning and academic achievement. Data that may be helpful in formulating a diagnostic impression of a child include information on the *DSM-5* diagnostic criteria for ADHD and results of multidisciplinary evaluations, Individual Educational Plan (IEP), achievement tests, grades, and written or verbal teacher narratives. Many of the ADHD rating scales discussed previously use teacher versions that can facilitate endorsement of diagnostic criteria or to assess for other conditions by school or after-school personnel

**Table 220-1** Sensitivity and Specificity of Rating Scales for the Diagnosis of ADHD

RATING SCALE	AGE (YEARS)	GENDER	EFFECT SIZE	95% CI
Conners Parent Rating Scale (CPRS-R:L-ADHD Index)—1997 Revised Version: Long Form, ADHD Index Scale	6–17	MF	3.1	2.5, 3.7
Conners Teacher Rating Scale (CTRS-R:L-ADHD Index)—1997 Revised Version: Long Form, ADHD Index Scale	6–17	MF	3.3	2.8, 3.8
Conners Parent Rating Scale (CPRS-R:L-DSM-IV Symptoms)—1997 Revised Version: Long Form, DSM-IV Symptoms Scale	6–17	MF	3.4	2.8, 4.0
Conners Teacher Rating Scale (CTRS-R:L-DSM-IV Symptoms)—1997 Revised Version: Long Form, DSM-IV Symptoms Scale	6–17	MF	3.7	3.2, 4.2
ACTeRS—Parent Version ADD-H: Comprehensive Teacher Rating Scale, Hyperactivity Subscale	6–14	MF	1.5	1.3, 1.7
ACTeRS—Parent Version ADD-H: Comprehensive Teacher Rating Scale, Attention Subscale	6–14	MF	2.0	1.8, 2.2
SNAP-III (Hyperactivity Subscale)	7–12	MF	5.1	3.9, 6.3
SNAP-III (Inattention Subscale)	7–12	MF	4.2	3.2, 5.2
SNAP-III (Impulsivity Subscale)	7–12	MF	5.5	4.3, 6.7
School Situations Questionnaire (SSQ-O-I)—Original Version, Number of Problem Settings Scale	6–11	F	1.3	0.5, 2.2
School Situations Questionnaire (SSQ-O-II)—Original Version, Mean Severity Scale	6–11	F	2.0	2.2, 3.5
Vanderbilt AD/HD Diagnostic Parent Rating Scale (VADPRS)	6–12	MF	N/A	N/A
Vanderbilt AD/HD Diagnostic Teacher Rating Scale (VADTRS)	6–12	MF	N/A	N/A

From Green M, Wong M, Atkins D, Taylor J, Feinleib M. *Diagnosis of Attention-Deficit/Hyperactivity Disorder. Technical Review No. 3.* Rockville, MD: Agency for Health Care Policy and Research; 1999. AHCPR Publication No. 99-0050.

(see Table 220-1). For children who are home-schooled or who spend a fair amount of time in after-school programs, clinicians may want to obtain information from the adults overseeing aspects of these programs, such as coaches, religious educators, after-school caregivers, and tutors.

An algorithm that may be helpful in evaluating a child for ADHD is shown in Figure 220-1. Patients with behavior problems or academic difficulties are scheduled for a complete physical examination, including hearing and vision testing, and are given assessment materials. The assessment materials may contain a pediatric intake history form, a request for school records, behavior rating scales, or educational materials. Once the assessment materials have been completed, rating scales scored, and a current physical examination documented, patients may be scheduled for an evaluation. The number of visits needed to complete the evaluation depends on the complexity of complaints and the amount of time available at each visit. The time reported to complete the overall evaluation, review background records, provide patient and family education, and establish a treatment plan ranges from 90 to 240 minutes. Offices have found multiple solutions for obtaining assessment materials and completing evaluations, including the use of a written assessment or computerized packets, longer appointments scheduled at designated times (eg, evenings, Saturday mornings, 1 particular clinic session every other week), partnerships with local schools, or the use of affiliated health personnel, including social workers or mental health professionals. The revised ADHD toolkit includes the Vanderbilt Rating Scales, both parent and teacher initial assessment and follow-up forms, and a sample cover letter.

### Evaluating Children Who Fail to Meet Attention-deficit/Hyperactivity Disorder Criteria

Some children may not meet diagnostic criteria for ADHD because they have fewer than the required number of DSM-5 criteria or because of conflicting reports among parents and school staff. In these circumstances, physicians should carefully evaluate for other conditions that may mimic ADHD (Box 220-2). In addition, physicians may want to counsel families on behavioral interventions. The *Bright Futures in Practice: Mental Health Tool Kit* website ([www.bright-futures.org/mentalhealth](http://www.bright-futures.org/mentalhealth)) contains current procedural terminology (CPT) billing codes for mental health services in the primary care setting and information on limit-setting, charting positive behavior, parenting anxious children, sleep hygiene, homework tips, and anger management that can assist families in caring for children with attentional and hyperactivity problems.

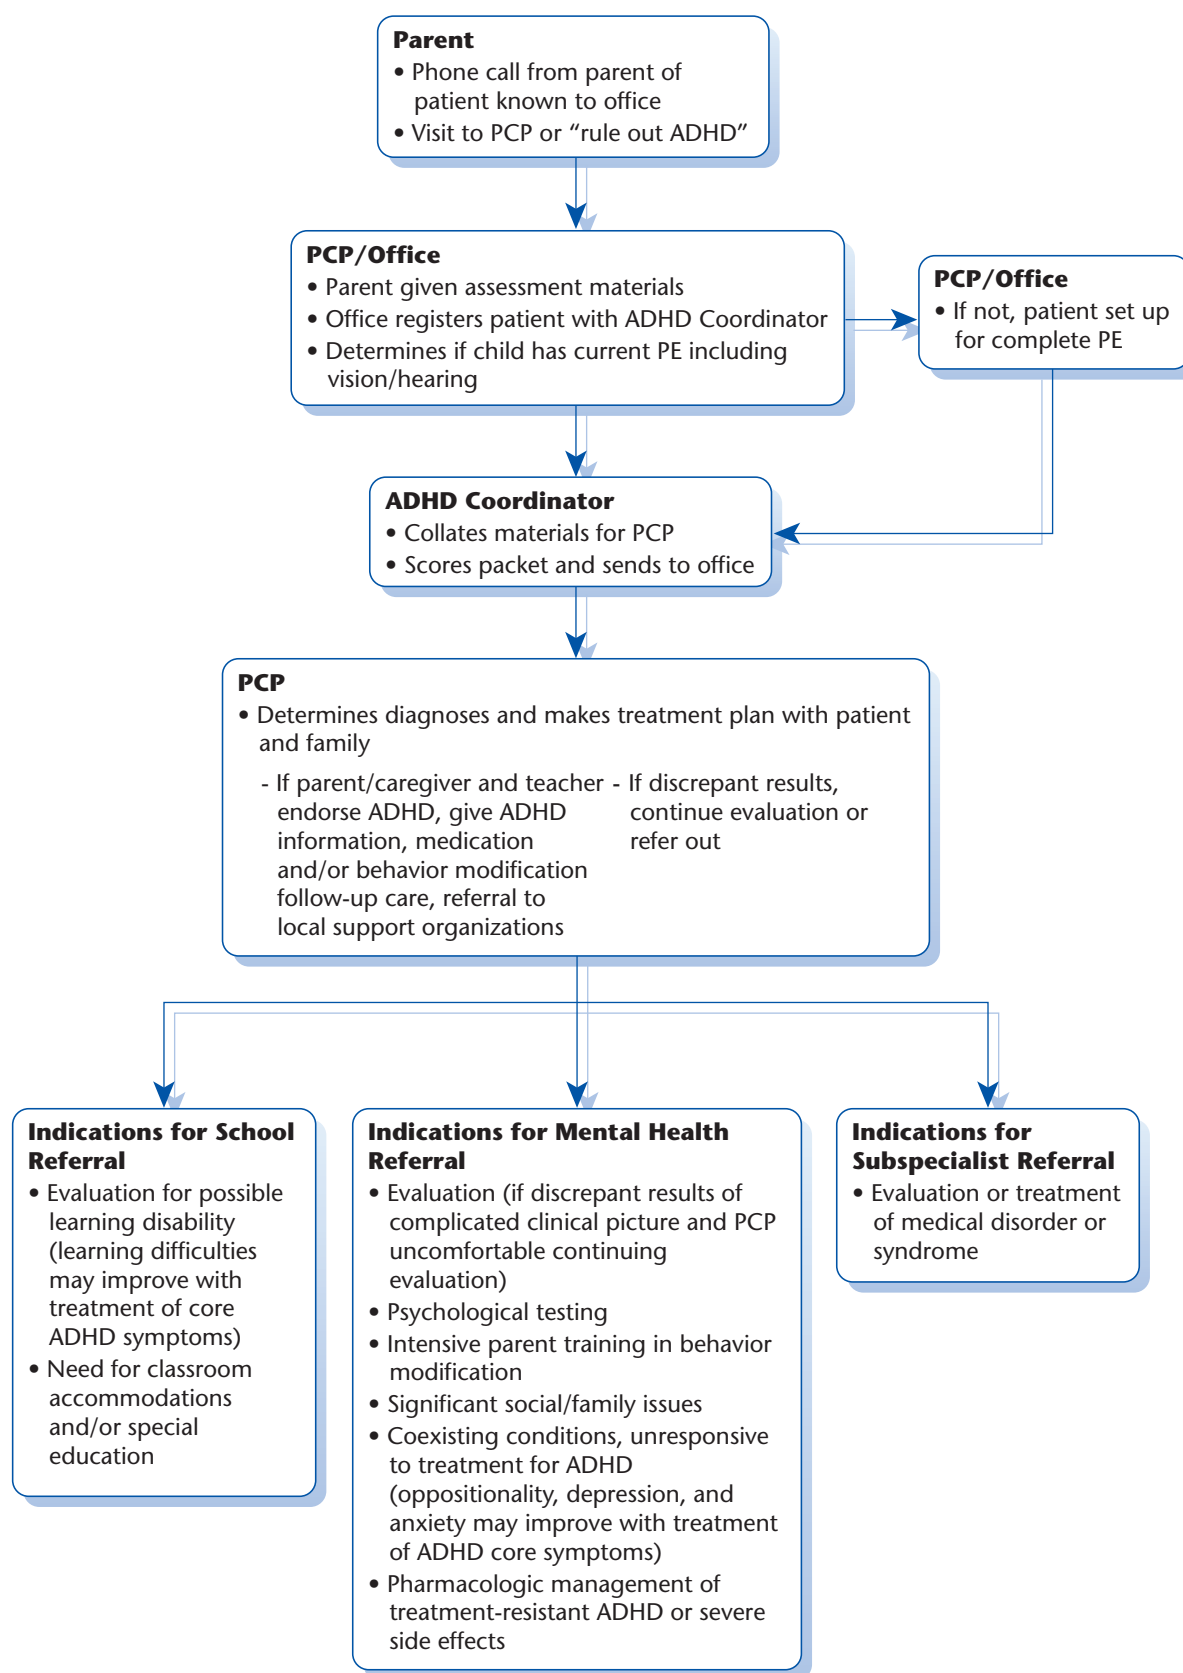

### Evaluating Co-occurring Conditions

Many children with ADHD have co-occurring behavioral or developmental conditions that may impair functioning, and the AAP guidelines recommend that all children undergoing an evaluation for ADHD be screened for these conditions. Several excellent tools are available that supplement a thorough history and

aid the primary care physician in screening for these conditions. Several of the ADHD ratings scales (eg, Vanderbilt Rating Scales, the Conners' Rating Scales-Revised, and the SNAP-IV Scales) include items that query for symptoms of depression/anxiety, oppositional-defiant disorder, and conduct disorders. Global behavioral rating scales such as the Pediatric Symptom Checklist, Child Behavior Checklist (CBCL), and the Behavior Assessment System for Children (BASC) can provide an overall perspective on a child's functioning, although they do not identify specific co-occurring conditions.

For the interested physician, rating scales also exist that specifically target the assessment of particular conditions, including depression, anxiety, and disruptive behaviors. Some examples include the Center for Epidemiological Studies Depression Scale for Children (CES-DC), the Multidimensional Anxiety Scale for Children, and the Eyberg Child Behavior Inventory. A detailed description of rating scales and screening tools specific to a variety of childhood mental health symptoms is available online ([www2.massgeneral.org/schoolpsychiatry/for\\_clinicians.asp](http://www2.massgeneral.org/schoolpsychiatry/for_clinicians.asp)). Questionnaires are also available that review DSM-5 criteria for most common childhood mental health disorders in a single instrument, such as the Child Symptom Inventory (CSI) and the DISC Predictive Scales.

The algorithm (Figure 220-1) directs the physician to refer to another professional (eg, developmental-behavioral pediatrician, mental health provider, or school-based psychologist) if a comorbid condition is suspected and if the physician is not equipped to evaluate sufficiently for these types of disorders in the office setting. Compiling a mental health resource list in the office can assist families in identifying local mental health providers on common insurance plans who can evaluate the child for possible comorbid mental health disorders. The Bright Futures toolkit provides a template for mental health referrals that can be used to structure referral information. For school referrals, parents should be directed to draft a letter requesting a multidisciplinary evaluation, including psychoeducational testing, if the history suggests a possible learning disability such as a reading disorder (dyslexia), mathematics disorder (dyscalculia), a disorder of written expression, or a communication disorder. An example of such a letter is included in the AAP ADHD toolkit. Handouts regarding school problems are available from Bright Futures, including one on common signs of learning disorders. Public schools are required to respond to family requests for evaluations within a specified period determined by local school district policies; even children attending private schools or who are home-schooled are eligible to receive an evaluation through their local school district. Families may also be referred to independent psychologists for psychoeducational evaluations through their insurance plans, but physicians should inquire whether their local school district accepts outside evaluations before making any referrals. In any event, the algorithm recommends that treatment for ADHD not be delayed while awaiting the results of referrals, given that symptoms of many of these conditions may improve with treatment of the ADHD core symptoms.

## MANAGEMENT

The AAP treatment guidelines recommend that families, school personnel, and physicians first recognize that ADHD is a chronic condition that will require ongoing, collaborative care. The Chronic Care Model, first developed by Wagner and colleagues and then modified for children by NICHQ, highlights the importance of patient and family education in the management of any chronic condition. Child and family education is particularly important in treating ADHD for several reasons. First, ADHD affects children across multiple domains of functioning. Second, parents are important partners in treatment, because they implement any treatment programs in the home setting. Third, children with ADHD are often cared for by a spectrum of health and school professionals; parents, especially with latency-age children, function as essential case managers in any ADHD management plan. Last, as children age, it becomes increasingly important that they take on the role of case manager with the ultimate outcome that they are ready to assume management of their ADHD upon adulthood. Handouts, book or website reference lists, or evening/weekend informational sessions in the office for children and families with ADHD are some educational mechanisms that have been used successfully by primary care physicians (see Tools for Practice at the end of the chapter). Additional strategies include educational and support groups such as Children and Adults with ADD (CHADD) or the Learning Disabilities Association (LDA), which provide important information to children and families regarding ADHD and its comorbid disorders, access to mental health and school-based services, and day-to-day lifestyle strategies to address the effect of ADHD on the child and family (see Table 220-2).

The AAP recommends that physicians, parents, and the child, in collaboration with school personnel, identify specific target outcomes in child functioning that they hope to effect through a treatment/management plan. Treatment strategies of choice delineated in the guidelines include evidence-based medication strategies or psychosocial interventions (or both) and are discussed in more detail below. The guidelines also state that child functioning should be systematically monitored over time to evaluate whether target outcomes are achieved or adverse side effects to treatment develop. If a child is not meeting targeted outcomes, then physicians, parents, and school personnel should collaboratively determine the validity of the diagnosis, adherence to all components of the treatment plan, and the possibility of any previously unidentified co-existing conditions. The ADHD toolkit includes sample management plans and follow-up parent and teacher forms to assist physicians in monitoring treatment.

Although the AAP guidelines specifically discuss medications and psychosocial interventions, 3 broad treatment modalities have been recommended in the literature, most often combined in what is commonly referred to as multimodal treatment. Multimodal treatment includes medications, psychosocial interventions directed at the child in the home and school

settings, and classroom assistance. These treatment types are reviewed in the subsections later in this chapter. Data are drawn from 4 sources: (1) the Agency for Healthcare Research and Quality's 1999 evidence report and technology assessment on the treatment of ADHD, (2) Jensen and Cooper's 2002 volume reviewing the state of the evidence regarding diagnosis and treatment of ADHD, (3) results from the recent Multimodal Treatment Study of Children with Attention-Deficit/Hyperactivity Disorder (MTA), and (4) the American Academy of Child and Adolescent Psychiatry's 2007 practice parameters for the assessment and treatment of children and adolescents with ADHD. In general, solid evidence supports the use of medication, behavioral modification strategies, and their combination in the treatment of ADHD. Other treatments have been studied although not as extensively, and the evidence supporting their use is less robust.

## Medication

Psychostimulants (eg, methylphenidate, dextroamphetamine, and the mixed salts of amphetamine) with careful medication management are the most commonly prescribed medications for ADHD (see Table 220-3). Although the mechanism of attentional enhancement is unknown, the psychostimulants are thought to have effects on central catecholamine pathways. In short-term studies, psychostimulants have been found to address the core symptoms of ADHD and improve sustained attention, organization, and motor inhibitor control. They also decrease disruptive behaviors (eg, fidgetiness, impulsive interrupting, aggression, relational interactions, oppositionality) in the classroom, on the playground, in social settings, and at home. With respect to cognitive functioning, these medications increase the accuracy of performance and improve short-term memory, reaction time, and seatwork computation; however, the effect size is smaller than that seen for behavioral challenges. An initial trial showed that stimulants, with careful medication management, were effective for approximately 70% of children diagnosed with ADHD. This percentage increases to over 90% if an alternative stimulant is tried following failure of an initial stimulant.

The most rigorous long-term trial of stimulant medications is the National Institute of Mental Health-funded MTA Study. This study was designed to compare the effects of 4 14-month treatments for school age children with ADHD-CT: (1) stimulants and medication management alone, (2) behavioral interventions, (3) combination therapy (stimulants plus behavioral interventions), or (4) assessment and referral to community care. The stimulant medication and management arm included careful titration of methylphenidate to the maximum dose that improved functioning with the fewest side effects, a 3-times daily schedule, manualized algorithm for dosage adjustment and trial of alternative medications, and monthly pharmacotherapist-performed clinical assessments with parent(s) and teacher. Results demonstrated that carefully managed stimulant medication, either alone or in combination with behavioral interventions,

RESOURCE	TARGET AUDIENCE	CONTENTS
American Academy of Pediatrics (AAP) Health Issues ( <a href="http://healthychildren.org/English/health-issues/conditions/adhd/Pages/default.aspx">healthychildren.org/English/health-issues/conditions/adhd/Pages/default.aspx</a> )	Parents	Fact sheets and articles for parents of children with ADHD
American Academy of Pediatrics (AAP) Caring for Children with ADHD: A Resource Toolkit for Clinicians ( <a href="http://shop.aap.org">shop.aap.org</a> )	Clinicians	For purchase; provides forms for the office, screening tools, and handouts for youth and families
American Academy of Pediatrics (AAP) ADHD: What Every Parent Needs to Know, 2nd ed ( <a href="http://shop.aap.org">shop.aap.org</a> )	Parents	Guidance from the AAP for parents of children with ADHD
Children and Adults with ADHD (CHADD) Website for public and members ( <a href="http://www.chadd.org">www.chadd.org</a> )	Parents, youth, clinicians	Provides support and information about ADHD
Children and Adults with ADHD (CHADD) National Resource Center on ADHD Website supported by a cooperative agreement between CHADD and the Centers for Diseases Control and Prevention ( <a href="http://www.help4adhd.org">www.help4adhd.org</a> )	Parents, youth	Provides information about ADHD, diagnosis and treatment, dealing with systems, educational issues, and living with ADHD
Massachusetts General Hospital School Psychiatry Program ( <a href="http://www2.massgeneral.org/schoolpsychiatry/screeningtools_table.asp">www2.massgeneral.org/schoolpsychiatry/screeningtools_table.asp</a> )	Clinicians	Provides a table of all screening tools and rating scales for symptoms of anxiety, social anxiety, obsessive-compulsive disorder, depression, bipolar disorder, suicide risk, ADHD, Asperger disorder, disruptive behaviors, and nonverbal learning disabilities
National Initiative for Children's Healthcare Quality ADHD Toolkit ( <a href="http://www.nichq.org/childrens-health/adhd/resources/adhd-toolkit">www.nichq.org/childrens-health/adhd/resources/adhd-toolkit</a> )	Clinicians	Provides forms for the office, screening tools, and handouts for youth and families; toolkit is available in English and Spanish
Center for Parent Information and Resources ( <a href="http://www.parentcenterhub.org/nichcy-resources">www.parentcenterhub.org/nichcy-resources</a> )	Parents, youth	Includes a limited amount of material on ADHD; good resource on IDEA and other comorbid disabilities
National Institute of Mental Health Health Information: ADHD ( <a href="http://www.nimh.nih.gov/health/topics/attention-deficit-hyperactivity-disorder-adhd/index.shtml">www.nimh.nih.gov/health/topics/attention-deficit-hyperactivity-disorder-adhd/index.shtml</a> )	Parents	Includes general information on ADHD
Sandra Rief ADHD ( <a href="http://www.sandrarief.com">www.sandrarief.com</a> )	Teachers, parents	Includes handouts and other resources specifically focused on classroom and home interventions to improve behavior and academic performance in children with ADHD
Section on Developmental Behavioral Pediatrics ( <a href="http://www2.aap.org/dbpeds">www2.aap.org/dbpeds</a> )	Clinicians	Includes general materials on behavioral-developmental problems including ADHD with a section that links to special article features, handouts for parents, and practice tools.
Bright Futures in Practice: Mental Health Volume II. Toolkit. ( <a href="http://www.brightfutures.org/mentalhealth/pdf/tools.html">www.brightfutures.org/mentalhealth/pdf/tools.html</a> )	Clinicians	Addresses mental health supervision in primary care, mental health across the developmental spectrum, identification of specific types of disorders (including ADHD), and diagnostic criteria, and provides forms for the office, screening tools, and handouts for youth and families
Office of Special Education and Rehabilitative Services, US Department of Education. ( <a href="http://www.ed.gov/teachers/needs/speced/adhd/adhd-resource-pt2.doc">www.ed.gov/teachers/needs/speced/adhd/adhd-resource-pt2.doc</a> )	Teachers, parents	Provides information on policies and research regarding educational interventions for children with ADHD.

Table 220-3

Stimulant Medications, Dosing, and Onset/Duration of Effects In Alphabetical Order<sup>a</sup>

ACTIVE INGREDIENT	DRUG NAME	DOSING	ONSET/DURATION OF EFFECTS
<b>AMPHETAMINE-BASED</b> Amphetamine, mixed salts (Dextroamphetamine/levoamphetamine)	Adderall Tablets ( <i>scored</i> ): 5, 7.5, 10, 12.5, 15, 20, 30 mg Generic available	Initial: 5 mg in AM Increase: 5 mg weekly Frequency: 1–3 doses/day Maximum recommended daily dose: 40 mg/day	Onset: 30 minutes Duration: 4–6 hours
	Adderall XR Extended release capsule ( <i>sprinkleable</i> ): 5, 10, 15, 20, 25, 30 mg Generic available	Initial: 5 mg in AM Increase: 5 mg weekly Frequency: 1 dose/day Maximum recommended daily dose: 30 mg/day	Onset: 30–45 minutes Duration: 8–12 hours
Amphetamine	Evekeo Tablet: 5, 10 mg ( <i>scored</i> )	Initial: 2.5–5 mg in AM Increase: 2.5–5 mg weekly Frequency: 1–3 doses/daily Maximum recommended daily dose: 40 mg/day	Onset: 30 minutes Duration: 4–6 hours
Dextroamphetamine	Dexedrine Tablet: 5 mg Dextrostat Tablet ( <i>scored</i> ): 5, 10 mg Generic Available	Initial: 2.5–5 mg in AM Increase: 2.5–5 mg weekly. Frequency: 2–3 doses/day Maximum recommended daily dose: 40 mg/day	Onset: 20–60 minutes Duration: 4–6 hours
	Dexedrine Spansules Sustained release capsule ( <i>can not be chewed</i> ): 5, 10, 15 mg	Initial: 5 mg in AM Increase: 5 mg weekly Frequency: 1–2 doses/day Maximum recommended daily dose: 40 mg/day	Onset: 60–90 minutes Duration: 6–10 hours
	Procentra Solution 5 mg/5 ml solution	Initial: 2.5–5 mg in AM Increase 2.5–5 mg weekly Frequency: 2–3 doses/day Maximum recommended daily dose: 40 mg/day	Onset: 20–60 minutes Duration: 4–6 hours
Lisdexamfetamine	Vyvanse Extended release capsule (can be dissolved in water): 20, 30, 40, 50, 60, 70 mg	Initial: 10–20 mg in AM Increase 10 mg weekly Frequency: 1 dose/day Maximum recommended daily dose: 70 mg	Onset: 50 min Duration: 10–14 hours
<b>METHYLPHENIDATE-BASED</b> Dexmethylphenidate	Focalin Tablets ( <i>scored</i> ): 2.5, 5, 10 mg Generic available	Initial: 2.5 mg in AM Increase: 2.5 mg weekly Frequency: 2–3 doses/day Maximum recommended daily dose: 30 mg	Onset: 20–30 minutes Duration: 4–5 hours
	Focalin XR Capsule ( <i>sprinkleable</i> ): 5, 10, 15, 20 mg, 25, 30, 35, 40 mg Generic available	Initial: 5 mg in AM Increase: 5 mg weekly Frequency: 1 dose/day Maximum recommended daily dose: 30 mg	Onset: 30 min Duration: 8–12 hours
Methylphenidate	Ritalin Methylin Tablets ( <i>scored</i> ): 5, 10, 20 mg Methylin Chewable tablets: 2.5, 5, 10 mg Methylin Oral solution: 5, 10 mg/5 mL Generic available	Initial: 5 mg in AM Increase: 2.5–5 mg weekly Frequency: 2–3 doses/day Maximum recommended daily dose: 50–60 mg depending on formulation	Onset: 15–20 minutes Duration: 3–5 hours

Continued

**Table 220-3****Stimulant Medications, Dosing, and Onset/Duration of Effects In Alphabetical Order<sup>a</sup>—cont'd**

Ritalin-LA Capsule ( <i>sprinkleable</i> ): 10, 20, 30, 40 mg Ritalin-SR Tablet: 20 mg SR Metadate ER Tablet: 10, 20 mg extended release Methylin ER Tablet: 10 mg extended release Metadate CD Capsule ( <i>sprinkleable</i> ): 10, 20, 30, 40, 50, 60 mg extended release Generic available	Initial: 10 mg in AM Increase: 10 mg weekly Frequency: 1 dose/day Maximum recommended daily dose: 60 mg	Onset: 30 minutes Duration: 6–10 hours
Concerta Capsule ( <i>noncrushable</i> ): 18, 27, 36, 54, 72 mg Generic available (make sure uses OROS-delivery system)	Initial: 18 mg in AM Increase: 18 mg weekly Frequency: 1 dose/day Maximum recommended dose: 72 mg	Onset: 30–45 minutes Duration: 8–12 hours
Daytrana Patch: 10, 15, 20, 30 mg patch	Initial: 10 mg worn daily for 9 hours beginning in AM Increase: 10 mg/9 hours weekly Frequency: Apply in AM as early as possible; worn daily for 9 hours Maximum recommended daily dose: 30 mg/9 hour Note: Skin sensitization (e.g., edema, papules, vesicles) that does not significantly improve within 48 hours or spreads beyond the patch site) may occur rarely and differs from an erythematous contact rash.	Onset: 60–120 minutes Duration: Variable, lasts 2–3 hours after patch removed
Quillivant XR Liquid: 25 mg/5 mL	Initial: 20 mg in AM Increase: 20 mg weekly Frequency: 1 dose/day Maximum recommended daily dose: 60 mg Start at 20 mg in am and increase by 10–20 mg increments until good control is achieved. Before administering dose, vigorously shake the bottle for at least 10 seconds to ensure the proper dose is administered. Maximum recommended dose: 60 mg	Onset: 45–60 minutes Duration: 10–12 hours

<sup>a</sup>Dose and frequency should be based on the child's schedule demands, metabolism, response, side effects, and parent/patient choice (eg, parents choosing to only provide medication during school times). Decision making may be documented in the medical record.

was effective in reducing the core symptoms of ADHD, reducing oppositional-aggressive and anxiety symptoms, and improving social skills.

The effects of stimulants are primarily compensatory and not curative. The effect lasts only as long as the child takes the medication. Unfortunately, very few long-term studies of the efficacy of the stimulant medications have been conducted; specific studies that are available are limited by their retrospective study design, lack of adherence measures, limited use of titration, and poor identification of comorbid conditions. A meta-analysis by Swanson and colleagues

concluded that the effect of stimulant medications over time on academic achievement was significantly less than the effect on behavior and cognition. In addition, many children with ADHD continue to show symptoms as they mature and enter adult life, including troublesome interpersonal relationships with family members and peers, career underachievement, and poor self-esteem. However, these earlier studies were not adjusted for the onset of treatment and the intensity of intervention offered. More recent retrospective studies demonstrate that treatment may protect against poor outcomes. For example, children treated

for ADHD with stimulant medication may be less likely to experiment with substances during adolescence compared with their untreated peers with ADHD.

The decision regarding the use of psychostimulants requires careful consideration of the associated benefits and risks. Common side effects of the psychostimulants include headaches, stomachaches, insomnia, and anorexia. The MTA study has documented a persistent growth delay, particularly when children were on higher and more consistent doses. Recent data suggest that the medications do not seem to consistently exacerbate tics. Less commonly reported adverse events include irritability, emotional lability or constriction, and compulsive picking of the nose or skin. Preschool children may experience more dysphoria and mood lability. These medications are also classified as schedule II medications with possible high abuse potential, although the research does not suggest a preferential use of stimulants in individuals with ADHD and substance use disorders.

Other safety concerns were the focus of a US Food and Drug Administration (FDA) review in 2006 and in 2011 and included cardiovascular and psychiatric complications related to the stimulant medications. Cardiovascular concerns included elevations in heart rate and blood pressure, and rare cardiovascular events such as stroke, myocardial infarction, and sudden death in children with preexisting cardiac disease. The panel concluded that children should be monitored for the emergence of hypertension. In addition, children starting on medication should have a complete history taken (including a family history of heart disease or arrhythmias, symptoms of shortness of breath, chest pain, dizziness, or palpitations on exertion) and a physical examination. In 2008, the AAP reiterated the role of an in-depth cardiac history and physical examination, with a follow-up electrocardiogram if indicated or a cardiology referral in cases with a family history or personal history of cardiac disease or symptoms prior to starting stimulant medications. Psychiatric concerns raised by the FDA review included new onset or acute exacerbation of aggressive symptoms and rare hallucinogenic symptoms, particularly visual hallucinations related to insects. Although all of these complications are rare, as with any medication, careful monitoring and vigilance are essential.

If parents, in concert with a child and physician, decide to try a psychostimulant, all must realize that medication choice, dose, and time interval must be carefully titrated to meet the needs of the individual child. In fact, several trials may be necessary before the most effective medication type and dose with the fewest side effects are identified. Carefully monitored titration that includes documentation of changes in ADHD symptoms and target outcomes and the development of any side effects is essential. Although the AAP guidelines do not stipulate the frequency of return visits, they do recognize ADHD as a chronic condition and recommend return visits to reassess academic performance, behavior, and side effects. More intensive visits may be necessary around predictable periods of change such as entry into middle or high school. Trials of medication are important to conduct but

should be scheduled so as to not overlap with the beginning of school terms, examinations, or family stressors. Families, children, and physicians should consider carefully the use of medication in the afternoons and evenings, on weekends, and during the summer, taking into account the severity of a child's dysfunction, the effect on family and peer relationships, cultural expectations, and the presence of any decrease in weight or height velocity. Sample follow-up forms are included in the ADHD toolkit. Management of possible side effects is delineated in Table 220-4.

Psychostimulants should be considered second-line therapy for preschool children aged 4 to 5 years, given results from the Preschool ADHD Treatment Study that suggest a strong response to behavioral interventions without medication. The guidelines support the use of stimulants if children still have moderate to severe impairment after implementing behavioral therapies. Dextroamphetamine has an FDA indication for preschool-aged children with ADHD, although there is more evidence for efficacy and safety in this age group than with methylphenidate. Preschool-aged children metabolize stimulants at a slower rate than older children and report more side effects, so lower doses should be prescribed to start and increased in smaller increments.

Regardless of the child's age, the AAP guidelines recommend certain nonstimulant medications as second-line treatment of ADHD after psychostimulants, including a selective norepinephrine reuptake inhibitor (atomoxetine), and the  $\alpha$ -agonists (clonidine and guanfacine) (see Table 220-5). These medications are currently considered second-line treatment because of fewer rigorous research trials, more adverse side effects, or less efficacy in comparison with the stimulants. In brief, the  $\alpha$ -agonists clonidine and guanfacine have moderate effects on hyperactivity and impulsivity, aggression, and tics. Given their effect on the cardiovascular system, care must be taken to not stop these medications abruptly, as this might result in rebound hypertension. In addition, sedation, particularly with clonidine, can be a significant problem. Bupropion, an atypical antidepressant not recommended in the AAP guidelines, has a few studies relating to its use in ADHD, and has been suggested as an option in children with comorbid depression. Atomoxetine was approved for the treatment of ADHD in 2003; common side effects include stomachache, nausea, appetite suppression, and weight loss. With increasing use of atomoxetine in the community over the last several years, warnings have surfaced regarding aggression, suicidality, reversible hepatotoxicity, and cardiac effects. The tricyclics have historically been used as second-line agents for ADHD, but their narrow toxic-to-therapeutic ratio has virtually eliminated their use in children with ADHD. Modafinil is currently approved for treatment of narcolepsy, and recent studies suggest its possible use in ADHD, although its application for approval for treatment with ADHD was denied by the FDA in 2006. No long-term studies on these medications in the management of ADHD have been completed. As with all medications, physicians should continue to monitor new scientific information about efficacy and adverse events.

**Table 220-4****Common Side Effects of Stimulant Medications and Recommended Clinical Management**

SIDE EFFECTS	RECOMMENDED CLINICAL MANAGEMENT
General	<ul style="list-style-type: none"> <li>• For mild side effects, allow 7–10 days for tolerance to develop.</li> <li>• Evaluate time-action and determine if timing of administration can be adjusted to minimize side effect.</li> <li>• Determine whether side effects are related to other disorders or current environmental stressors and adjust accordingly.</li> <li>• If these strategies fail, consider an alternative stimulant.</li> </ul>
Weight loss/anorexia	<ul style="list-style-type: none"> <li>• Administer medication at or after a meal.</li> <li>• Try calorie enhancement strategies, such as high-protein instant breakfasts, protein bars, etc.</li> <li>• Get eating started with any highly preferred food before giving regular foods.</li> <li>• Allow grazing in the evening when appetite suppression wanes.</li> <li>• Change stimulant medications.</li> <li>• Consider drug holidays.</li> </ul>
Dizziness	<ul style="list-style-type: none"> <li>• Monitor blood pressure and pulse.</li> <li>• Encourage adequate hydration.</li> <li>• If associated only with peak drug effect, try longer-acting preparation.</li> </ul>
Insomnia/nightmares	<ul style="list-style-type: none"> <li>• Establish bedtime routine.</li> <li>• Omit or reduce last dose or change to standard, short-acting version if using longer-acting preparation.</li> <li>• Administer medication earlier in the day.</li> <li>• Try a different stimulant.</li> <li>• Give “Parenting Tips for Better Sleep” handout (sample available at <a href="http://www2.aap.org/sections/dbpeds">www2.aap.org/sections/dbpeds</a>).</li> </ul>
Dysphoric mood, emotional constriction	<ul style="list-style-type: none"> <li>• Consider additional medication as a last resort.</li> <li>• If peak effect, reduce dose, or switch to longer-acting preparation.</li> <li>• Evaluate when occurs. See below for guidance on rebound.</li> <li>• Try a different stimulant.</li> <li>• Consider comorbid anxiety or depression disorders requiring alternative or adjunctive treatment.</li> </ul>
Rebound	<ul style="list-style-type: none"> <li>• Consider additional medication as a last resort.</li> <li>• Try to decrease precipitous drop in blood levels by using a “stepped down” dosage at the end of the day through increasing morning long-acting dose or adding a smaller dose of short-acting medication toward the end of the day.</li> <li>• Switch to longer-acting preparation.</li> <li>• Combine longer-acting and short-acting preparations.</li> <li>• Overlap stimulant dosing.</li> </ul>
Tics	<ul style="list-style-type: none"> <li>• Conduct drug trial at different doses, including no medication, to be sure tics are drug related.</li> <li>• For mild tics that abate after 7–10 days, reconsider risk vs benefit, and negotiate a new informed consent with the parent/guardian.</li> <li>• Conduct drug trial to see if tics abate with another stimulant.</li> <li>• Consider nonstimulant treatment, such as clonidine, alone or in combination with a stimulant, or refer to mental health specialist or neurologist skilled in the management of tics.</li> <li>• If tics appear suddenly after a sore throat or sinus infection, consider strep-associated tics or PANDAS (Pediatric Autoimmune Neurologic Disorders Associated with Strep) and treat with appropriate antibiotic.</li> </ul>
Psychosis	<ul style="list-style-type: none"> <li>• Check that correct dose is being administered.</li> <li>• Discontinue stimulant treatment.</li> <li>• Assess for presence of coexisting bipolar or thought disorder.</li> </ul>
Skin irritation	<ul style="list-style-type: none"> <li>• Consider alternative treatments, or referral to a mental health specialist.</li> <li>• Skin irritation may arise with use of the patch, either because of hypersensitivity to methylphenidate or other components in the product (eg, acrylic adhesive).</li> <li>• Rotation of the patch may help.</li> <li>• Use of the patch may lead to contact sensitization indicative of allergic contact dermatitis and should be suspected if erythema is accompanied by evidence of a local and intense reaction with edema, papules, or vesicles or if physical manifestations spread beyond the area of the patch.</li> <li>• Use should be discontinued, allergic diagnostic testing considered, and use of an oral methylphenidate under close medical supervision initiated.</li> </ul>

**Table 220-5** Additional Medications for Treatment of ADHD (in alphabetical order by drug class)

DRUG	FORM	DOSING	COMMON SIDE EFFECTS	DURATION OF BEHAVIORAL EFFECTS	BENEFITS	PRECAUTIONS
ALPHA AGONISTS						
Catapres® or Generic Clonidine	Tablets: 0.1, 0.2, 0.3 mg	Initial: 0.05 mg at bedtime Increase: 0.05 mg every 3–7 days Frequency: 2-4 doses/day Maximum recommended dose: 0.4 mg/day	Sleepiness, irritability, hypotension, dizziness, dry mouth, constipation.	Tablet: 3–6 hours	Helpful for ADHD patients with significant comorbid tics; may be helpful for ADHD patients with aggression or insomnia.	Side effects include sedation, dizziness, nausea, orthostatic hypotension, depression, nightmares. Sedation decreases over time. To avoid daytime tiredness, give tablet initially at night. Sudden discontinuation could result in rebound hypertension. When discontinuing, the total dose should be tapered in decrements of no more than 0.1 mg every 3–7 days. See FDA for other precautions.
Catapres or Generic Clonidine	Patches TTS-1 TTS-2 TTS-3	Initial: TTS 1 patch Increase 0.1 mg every 2 weeks Frequency: change every 5–7 days; rotating sites on back	Sleepiness, irritability, hypotension, dizziness, dry mouth, constipation. Local-zed skin reactions with patch	Patch: 1–5 days		
Kapvay Clonidine Extended Release	Tablets: 0.1, 0.2 mg	Initial: 0.1 mg tablet at bedtime. Increase: 0.1 mg weekly Frequency: 2 doses/day; with either an equal or higher split dosage being given at bedtime. Maximum recommended daily dose: 0.4 mg/day	Sleepiness, irritability, hypotension, dizziness, dry mouth, constipation.	12–24 hours	May be helpful for ADHD patients either as monotherapy or as an adjuvant therapy.	
Tenex or Generic Guanfacine	Tablet: 1, 2 mg	Initial: 0.5 mg at night. Increase: 0.5 mg weekly. Frequency: Give as 1–2 dose/day Maximum recommended daily dose: 3 mg/day	Irritability, tiredness, confusion at higher doses, agitation.	About 24 hours in the body, but must be taken 2 (or 3) times/day.	May cause less sedation and irritability than clonidine.	Side effects include sedation, dizziness, nausea, orthostatic hypotension, insomnia, agitation, headaches, nightmares. Sedation decreases over time. To avoid daytime tiredness, starting dose given at bedtime and increased slowly. Sudden discontinuation could result in rebound hypertension; wean slowly. See FDA for other precautions.
Intuniv Guanfacine Extended Release	Tablet: 1, 2, 3, 4 mg	Start with 1 mg and increase by no more than 1 mg/week. Maintain dose in range of 1–4 mg/day.	Irritability, tiredness, confusion at higher doses, agitation.	24 hours	May be helpful for ADHD patients as monotherapy or as an adjuvant therapy. May cause less sedation and irritability than clonidine.

Table 220-5 Additional Medications for Treatment of ADHD (in alphabetical order by drug class)—cont'd

DRUG	FORM	DOSING	COMMON SIDE EFFECTS	DURATION OF BEHAVIORAL EFFECTS	BENEFITS	PRECAUTIONS
SELECTIVE NOREPINEPHRINE REUPTAKE INHIBITORS						
Strattera	Capsules: 10, 18, 25, 40, 60, 80, 100 mg	Initial: 0.5 mg/kg in AM Increase: Frequency: Usually single dose per day but can split if GI issues or fatigue.	Nausea, vomiting, fatigue, decreased appetite decreased, dizziness, tiredness, aggression, constipation, dry mouth, insomnia,	18–24 hours	Helpful as second-line treatment for ADHD or for ADHD patients with comorbid anxiety	If sedation, consider moving initial dosing regimen to evening. Common side effects include fatigue, lightheadedness, GI upset, dry mouth, sweating, insomnia, weight loss, headache. Rare side effects include mood swings, sexual and menstrual changes, 2 cases of liver damage. See FDA for other precautions.
Atomoxetine		Recommended maximum daily dosage: 1.44 mg/kg/day or 100 mg/day	decreased libido, and mood swings			

### Psychosocial Interventions

Several studies show that psychosocial interventions, predominantly using behavioral management principles, decrease ADHD symptoms and impairment. Behavioral interventions usually consist of parent training programs for use at home, child-focused intensive summer camp programs, behavioral modification in the classroom, and peer interventions. In general, these interventions focus less on improving the core symptoms of ADHD (inattention, impulsivity, and hyperactivity) and instead seek to improve parenting practices, school functioning, and peer relationships. Common to many of these approaches is the use of behavioral techniques such as positive reinforcement, time-out, response costs, or token economies (see Table 220-6). Individual psychotherapy and play therapy have not been shown to reduce core ADHD symptoms in children; however, there is some evidence for cognitive therapy in adults. These nonbehavioral therapies may benefit some children with ADHD who have associated mental health conditions responsive to these therapies.

The MTA trial examined the efficacy of behavioral interventions compared to stimulant medication alone or in combination with behavioral therapy. Components of the behavioral interventions in the MTA Study included 27 group and 8 individual parent training sessions, child participation in an 8-week intensive therapeutic all-day summer camp program, and teacher consultation plus 12 weeks of a half-time behaviorally trained paraprofessional aide in the classroom. The results of this trial have been interpreted in

conflicting manners, with some suggesting that the MTA study demonstrates the superiority of medication either alone or in combination with behavioral therapy, and others highlighting the potential importance of psychosocial interventions. Medication in combination with behavioral approaches was found to be particularly effective for children with ADHD and with associated anxiety disorder, ADHD with both anxiety and oppositionality, or children in single-parent households or from low-income families. Combined treatment was also superior to medication alone for outcomes such as parent-child relations and consumer satisfaction.

Several advantages of behavioral interventions that deserve mention include: (1) use in combination with medication may allow for a reduced dose of medication; (2) the therapeutic benefits of stimulant medication usually occur during the day, whereas behavioral interventions may be used in the late afternoon or evening in place of an additional dose of medication; (3) disruptive disorders that commonly co-occur with ADHD have been shown to respond to behavioral modification; (4) psychosocial treatment may help to enhance parents' positive perception of their children and of their own parenting abilities; and (5) the results for medication last only as long as a child continues to take it, whereas behavioral interventions may extend over time. In addition, not all children and families accept the use of long-term medication treatment for ADHD or respond to stimulants. Finally, medications may be more expensive than behavioral interventions in the long run.

**Table 220-6**

### Evidence-Based Behavioral Treatments for Attention-deficit/Hyperactivity Disorder

INTERVENTION TYPE	DESCRIPTION	TYPICAL OUTCOME(S)	MEDIAN EFFECT SIZE <sup>a</sup>
Behavioral parent training (BPT)	Behavior-modification principles provided to parents for implementation in home settings	Improved compliance with parental commands; improved parental understanding of behavioral principles; high levels of parental satisfaction with treatment	0.55
Behavioral classroom management	Behavior-modification principles provided to teachers for implementation in classroom settings	Improved attention to instruction; improved compliance with classroom rules; decreased disruptive behavior; improved work productivity	0.61
Behavioral peer interventions (BPI) <sup>b</sup>	Interventions focused on peer interactions/relationships; these are often group-based interventions provided weekly and include clinic-based social-skills training used either alone or concurrently with behavioral parent training and/or medication	Office-based interventions have produced minimal effects; interventions have been of questionable social validity; some studies of BPI combined with clinic-based BPT found positive effects on parent ratings of ADHD symptoms; no differences on social functioning or parent ratings of social behavior have been revealed	

<sup>a</sup>Effect size = (treatment median – control median)/control SD.

<sup>b</sup>The effect size for behavioral peer interventions is not reported, because the effect sizes for these studies represent outcomes associated with combined interventions. A lower effect size means that they have less of an effect. The effect sizes found are considered moderate. From American Academy of Pediatrics Subcommittee on Attention-deficit/Hyperactivity Disorder, Steering Committee on Quality Improvement and Management. ADHD: clinical practice guideline for the diagnosis, evaluation, and treatment of attention-deficit/hyperactivity disorder in children and adolescents. *Pediatrics*. 2011;128(5):1007–1022.

Disadvantages of behavioral interventions primarily reflect challenges related to accessing these services. The psychosocial interventions with demonstrated effectiveness in the literature are usually quite intensive, including the behavioral intervention in the MTA study, 9-week summer day camp for children with ADHD, and intensive social-skills training sessions for parents and children. These types of intensive interventions are often difficult to access for most children because of a lack of identified mental health providers trained in these programs, lack of insurance coverage, and limited services available through schools.

Physicians caring for children with ADHD can access these types of services through several mechanisms. First, mental health professionals are increasingly being trained in behavioral modification techniques; knowing which providers in the community offer these types of services is essential. Physicians may also choose to provide parenting programs in their office setting or through their health plan. Several practices that participated in a year-long quality improvement program on ADHD care sponsored by the NICHQ, AAP, and Carolina Center for Children's Healthcare Improvement chose to implement behavioral intervention programs for parents in their office settings using available protocols. Behavioral intervention programs for the school setting have also been published and are available online (see [www.ed.gov/teachers/needs/speced/adhd/adhd-resource-pt2.doc](http://www.ed.gov/teachers/needs/speced/adhd/adhd-resource-pt2.doc) for examples of such materials). These types of programs can be requested through the schools as described below.

### School-Based Services

School-based services are a critical part of a comprehensive management plan for several reasons. First, the behaviors observed in children with ADHD are contextually driven and often manifest themselves more in concentration-demanding situations such as school. Communication with school personnel is essential for making the diagnosis of ADHD and for optimal titration of medication, if prescribed. Second, a solid evidence base supports the effectiveness of highly structured behavioral management strategies implemented by school staff in addressing many of the behavioral and organizational challenges experienced by children with ADHD. These interventions can range from daily report cards to point or token systems with primary outcomes consisting of following classroom rules, complying with teacher requests, improving peer interactions, and increasing classroom productivity. The effects tend to be greater for more intensive programs in special class settings, though gains are also seen in regular classrooms. Third, comorbid learning disabilities are not uncommon, and physicians, families, and school personnel should closely monitor each child to ensure that the problems associated with ADHD are not masking coexisting learning disabilities that would require formal testing for learning problems, identification of areas of disability, and specific learning interventions under an IEP as stipulated under the Individuals with

Disabilities Education Act (IDEA) (Public Law 94-142, amended in 1997 under Public Law 105-17). Learning disabilities coexistent with ADHD usually fall into the category of language-based disorders of learning or impaired mathematics performance.

A child with ADHD who does not meet criteria for a specific learning disability may still commonly experience challenges with academic work. The child may demonstrate motor challenges, including dysgraphia, with resultant poor handwriting, and problems related to poor visual-motor abilities (eg, copying materials off of a board or textbook onto paper). Other challenges include inconsistent performance, delayed acquisition of core reading and math skills, low productivity, delay in rapid retrieval of facts, difficulty with higher-level problem solving involving multiple steps, impaired reading comprehension, and poor metacognitive abilities (eg, organization, time management, breaking tasks down into smaller components). These problems can often be inappropriately attributed to laziness or lack of motivation. Education of the child, parents, and school personnel regarding the inadvertent labeling of behaviors related to these difficulties as oppositionality rather than as cognitive challenges associated with ADHD is critical. Interventions such as direct remediation of learning problems, bypass strategies, and metacognitive skills training are all-important academic tools in planning curricula for children with ADHD. Intervention practices not specific to ADHD have been developed and are reviewed in Kavale and Forness' monograph titled *Efficacy of Special Education and Related Services*.

Children can access school-based services via their local public school system through several mechanisms. Individual teachers often modify the curriculum or classroom environment to address a child's needs. Many schools have an interdisciplinary council (eg, student study team, multidisciplinary assessment team) that informally reviews a child's academic performance and behavior and suggests possible remediation. Through Section 504 of the Rehabilitation Act, school systems are mandated to provide accommodations in the mainstream classroom. Under IDEA, school systems also provide a continuum of special education services, ranging from accommodations in the mainstream classroom to a special day class in a public or private placement. Children with ADHD often qualify for special education services because of a coexisting specific learning disability, language disorder, or severe emotional disturbance. In 1991, the US Department of Education also stated that individuals with ADHD might be considered disabled under the "Other Health Impaired" categorization under IDEA, potentially increasing access to school-based special education services for children with ADHD.

Because academic underachievement is so commonly seen in children with ADHD, physicians need some comfort level with the types of interventions available through the public school system. Accommodations requested through a 504 plan or IEP should address a child's individual areas of need. For example, children with ADHD often need preferential seating close to the teacher and daily or weekly

progress reports for both behavior and academic performance sent to the home to allow for close monitoring of school success. Children may also need reduction of the amount of written work, modified homework assignments, or extra time to complete assignments or tests. Organizational difficulties may require supervision of the writing of homework assignments in a planner, an extra set of books at home, and assistance breaking large projects into small steps. Problems with handwriting may indicate a need for access to a computer for written work, copies of teacher lectures, or electronically recorded textbooks. If behavior interferes with the individual child's academic performance or the ability of other children in the classroom to learn, then a behavioral intervention plan is necessary that delineates what behaviors a child displays, factors that escalate or dampen the behavior, and appropriate behavioral interventions. If a child does have a coexisting learning or language disorder, then specific interventions for these disorders should also be included in any plan. Consideration should be given to the appropriate educational placement of a child (eg, mainstream classroom with or without assistance from a resource specialist, special day class, private nonpublic placement). Sample letters requesting a 504 plan or IEP as well as additional information on these programs are available in the ADHD toolkit and on the Bright Futures website.

Concerns are often raised by physicians, parents, and teachers that these types of accommodations may lead to children who feel entitled to extra assistance and will not be able to function adequately in college or the workplace setting. For these reasons, accommodations must be provided within the context of teaching a child to understand his or her own strengths and weaknesses and develop compensatory strategies for addressing their areas of challenge.

### **Alternative Treatments for Attention-deficit/Hyperactivity Disorder**

Alternative approaches to treatment for ADHD abound and have included dietary recommendations, ocular training, and hypnotic and biofeedback regimens. Some treatments have been demonstrated to be efficacious (eg, oligoantigenic diet or restricted elimination diet in ADHD children with food sensitivities), disproven (eg, sugar in the diet), or are potentially unsafe (eg, megavitamin dosages, chelation). Most lack a substantial evidence base for or against their use at this time. Three new studies deserve mention. One recent randomized controlled trial of a restricted elimination and rechallenge diet (mainly rice, vegetables, meat, pears, and water) found a reduction of at least 90% of symptoms in 64% of children with ADHD. Issues with blinding and effort to make sure children adhered to the diet were noted by the authors. A published meta-analysis of 10 randomized clinical trials found a modest effect size for omega-3 fatty acid supplementation compared to placebo. Another trial found neurofeedback to be as effective as methylphenidate for the treatment of ADHD symptoms. If a decision is made to try these types of modalities, the AAP

guidelines recommend similar monitoring of symptoms and functioning using rating scales, histories, and physical examinations. A full discussion of these modalities is beyond the scope of this chapter but an excellent review is available (see Suggested Readings).

### **CASE REPORT: RESOLUTION**

Following a detailed history and physical examination, you are increasingly convinced that Bethany's talkativeness, endless energy, and poor school performance may represent ADHD. You are concerned that her mood and somatic complaints may represent depression, and her early reading difficulties may represent a learning disability. You decide to have her guardian and teacher(s) complete the Vanderbilt Rating Scales, given that they are available in the public domain, facilitate documentation of diagnostic criteria, and can be used to explore the possibility of a comorbid depressive disorder. You compose a brief letter to her teachers using the sample form in the ADHD toolkit as a guide to request their assistance in completing the scales, and you ask that they send any additional school information, such as grades, achievement test results, or narrative summaries, to you. You also instruct Bethany's guardian to draft a letter to her school to request a multidisciplinary assessment for learning disabilities. You elect not to pursue any laboratory or imaging tests, given that Bethany's history and physical examination do not suggest cardiac disease, vision or hearing difficulties, or another diagnosis that would be assessed by such tests.

On a follow-up visit, you review the results of the Vanderbilt Rating Scales and school information obtained from her teacher with Bethany and her guardian. You note that in both her parent and teacher scales she meets 6 of 9 criteria for the predominately hyperactive/impulsive subtype. You also note that she screens positive on 3 of 7 anxiety or depression symptoms. Narrative information from her homeroom teacher corroborates the rating scales and affirms her guardian's concerns that her grades have been slipping. The letter also informs you that the school has scheduled Bethany for psychoeducational testing in the near future. You inform Bethany and her guardian that she meets criteria for ADHD and discuss cause and possible treatment options. You provide educational materials on ADHD that you compiled from the AAP and other selected sites. You relate your concerns that Bethany might be displaying signs of depression. In collaboration with the family, you structure a treatment plan and goals for Bethany using the sample management plan in the ADHD toolkit. The treatment plan includes a prescription for a psychostimulant, a referral to a child psychologist to assess for depression, and a community referral to a local program that sponsors parent behavioral training courses. With Bethany's and her guardian's permission, you draft a letter to the school to inform them of Bethany's diagnosis and to encourage their ongoing collaboration with you in Bethany's care. You also distribute Vanderbilt Follow-up Scales to her guardian and teacher(s) to document any changes in

her symptoms that will assist you in titrating her medication dosage optimally.

At her next several visits, you review Bethany's progress in meeting her goals. You note substantial improvement in her total symptom scores and in her average performance scores on the Vanderbilt Rating Scales. Bethany relates that she initially had stomach pain and headaches with the medication, as you had anticipated with the family at the previous visit, but that these symptoms have resolved. You also check and find that her pulse and blood pressure are within normal limits. Bethany states that she is feeling better about her academic work. Her guardian states that Bethany has been less talkative at home and more organized and focused with her homework since she implemented a behavioral management plan. Next, you review the results of the psychology referral with the family, which confirms a diagnosis of ADHD but does not support a diagnosis of depression or anxiety. Bethany notes that her depressive symptoms have decreased as her ability to succeed at school and on homework have improved with medication and other interventions. However, Bethany continues to struggle with reading. Several weeks later, you receive the results of the psychoeducational testing from the school. You note that Bethany meets criteria for a reading disability and that an IEP was established to assist Bethany in improving her reading abilities and to provide classroom accommodations (eg, seating in front, reduction in distractions, and a daily homework report card). You are pleased with Bethany's progress to date, and you make plans with the family to continue to monitor her closely in the future.

Over time, your goal is to help Bethany and her aunt identify Bethany's strengths as well as areas of challenge related to her ADHD and reading disability. In concert with any mental health professionals and school personnel involved in her care, you will partner to help Bethany develop strategies to address her areas of challenge and to best manage her ADHD symptoms so that she can become a productive, healthy adult.

## CONCLUSION

Attention-deficit/Hyperactivity Disorder is a common, chronic disorder of childhood and adolescence affecting multiple domains of functioning and often continuing into adulthood. Diagnosis and treatment are complicated by the lack of a biological marker, high rates of comorbid conditions, and the need to coordinate care across multiple settings. However, children with ADHD can successfully function in the home and school settings. Families, school personnel, and physicians often observe that children whose symptoms are recognized, assessed, and managed at an early age will show improved self-esteem and success in the classroom, both of which are essential for normal psychosocial and educational development. Although as many as 70% of children and adolescents continue to be symptomatic in adulthood, outcomes are improved with familial stability and support, an ongoing therapeutic relationship with a physician, and a higher IQ. The primary care physician's role is to help children, in partnership with their families and teachers, achieve this goal.

General guidelines for referral are provided in the When to Refer section below. These guidelines should be modified depending on the constellation of symptoms and coexisting conditions a particular child exhibits and the skill-set and comfort level of the primary care physician in managing the treatment of ADHD and any coexisting conditions. If assistance is needed in evaluating a child, then referral to a mental health professional, school professional, or medical specialist might be indicated. Referral to a mental health professional is indicated for pharmacologic management of treatment-resistant ADHD, more intensive behavioral modification training for the home setting than can be provided in the primary care office, or psychosocial or pharmacological interventions for a coexisting mental health disorder. Mental health professionals may also play an important role if the family is experiencing significant familial stress related to a child's ADHD or if psychopathology exists in the family, including domestic violence, substance abuse, and other conditions. Schools are essential partners in the diagnosis and management of ADHD, whether a child has a coexisting learning disability. Children with severe emotional impairment secondary to any mental health disorder, including ADHD, are also eligible for development of an intensive behavioral management plan under the IEP mechanism through their local school district. Referral to a medical subspecialist is indicated if the history or physical examination suggests evaluation for an additional medical disorder.

## WHEN TO REFER

- Evaluation (if discrepant results or complicated clinical picture exists and the primary care physician is uncomfortable continuing evaluation)
- Psychological testing
- Intensive parent training in behavior modification
- Significant social and family issues
- Coexisting conditions that are unresponsive to treatment for ADHD (oppositionality, depression, and anxiety may improve with treatment of ADHD core symptoms)
- Pharmacologic management of treatment-resistant ADHD or severe side effects
- Major depressive disorder as an immediate referral before initiating treatment for ADHD
- Active substance abuse

## WHEN TO ADMIT

The core symptoms of ADHD should not necessitate admission to a medical or psychiatric hospital. Indications for admission would include:

- Symptoms related to any of the mental health conditions that may co-occur with ADHD
- Adverse event secondary to medication for the treatment of ADHD
- A medical condition resulting from the core symptoms of inattention, hyperactivity or impulsivity associated with ADHD (eg, accidental injury)

## Chapter 221

## AUTISM SPECTRUM DISORDER

Elizabeth M. Kryszak, PhD; James A. Mulick, PhD;  
Eric M. Butter, PhD

Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder characterized by significant developmental delays in language and communication skills; abnormalities in language when it does develop; significant impairments in reciprocal social behavior; a restricted and narrow repertoire of interests and behaviors; ritualized and repetitive behavior patterns; and stereotyped, destructive, and disruptive behavior problems. The diagnosis is made based on the child's behavior, in part historically and in part by concurrent observation or behavior reporting. Children with ASD often function within the intellectually disabled range of general intellectual ability and have limited adaptive behavior. ASD is most often a pervasive and lifelong disability that is difficult to treat.

Because ASD is a categorical disorder, based on observation and historical report rather than quantitative measurement, the description of diagnostic criteria and methods for making a diagnosis have shifted greatly over the years. As a result, there have been dramatic shifts in the estimated prevalence of the disorder since data were first collected in the late 1960s. Historically, autism was thought to occur at a rate of 2 to 5 in every 10,000 children. By the early 2000s, prevalence estimates rose to 10 to 20 in every 10,000

children. More recent data indicate that the incidence of autism may be far greater, with estimated rates ranging from 110 to about 147 per 10,000 children. This trend of steadily increasing rates of autism has caused controversy as to whether increases are related to a truly greater incidence or to other factors, such as greater awareness, changing diagnostic criteria, earlier age at diagnosis, changing diagnostic methods, methodological differences in data collection, and even increased parent demand for the diagnosis so the child can meet treatment and educational service eligibility criteria. It should be noted that despite widely varying prevalence rates, ASD has remained far more common in boys than in girls, with a ratio ranging between 4:1 and 5:1 over the last decade.

The most debilitating aspect of autism is comorbid intellectual disability (ID). Although previously thought to occur in about 70% of children with ASD, the prevalence of ID has most recently been reported to occur at a much lower estimated rate of approximately 31% of all cases of autism. Intellectual disability remains the most difficult aspect of autism to ameliorate, and the presence of ID with autism has the poorest prognosis. Children with both autism and ID fail to benefit from conventional social and educational experiences—the same experiences that allow other children opportunities for cognitive growth and learning. Other comorbid conditions include anxiety, attention problems, seizures, gastrointestinal (GI) problems, and sleep difficulties. Children with autism also often have associated behavioral problems, including pica, self-injury, and aggression.

No known, single cause of autism has been found, and most researchers have accepted that autism likely has multiple causes. Twin studies have indicated a heritability of 38% to 90%, indicating a strong genetic link in ASD, although several pre- and postnatal environmental factors have also been linked to an increased risk for ASD. These include increased maternal stress, maternal age, pre- and postnatal infections, and exposure to neurotoxins. Therefore, evidence is growing for a complex epigenetic relationship that affects neurologic development as early as the prenatal period, and the search for both autism susceptibility genes and environmental catalysts is ongoing. It should, however, be noted that there is no credible evidence supporting the theory that vaccines, such as the measles, mumps, and rubella vaccine, cause ASD. Outside of a specific biological cause, several medical and genetic conditions have been associated with autism, including fragile X syndrome, Cornelia de Lange syndrome, Rett's syndrome, Prader-Willi syndrome, Angelman syndrome, Smith-Lemli-Opitz syndrome, CHARGE syndrome, and tuberous sclerosis.

## DIFFERENTIAL DIAGNOSIS

Diagnostic criteria were significantly reorganized in the fifth edition of the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders (DSM-5)*. In *DSM-IV*, the cluster of symptoms most often associated with ASD was split into 3 diagnostic categories: autistic disorder, Asperger disorder, and pervasive developmental disorder not otherwise

specified (PDD-NOS). Childhood disintegrative disorder and Rett's disorder were also included in the *DSM-IV* under the category of pervasive developmental disorders as separate diagnostic categories with a similar set of symptoms. Autistic disorder described a child who met full diagnostic criteria in terms of language deficits, deficits in social interaction, and repetitive, restricted behaviors. Asperger disorder was diagnosed when typical language development was present in the context of impaired social interactions and repetitive, restricted behaviors. The diagnosis of PDD-NOS was reserved for cases in which the central features of language delay, impaired reciprocal social interaction, or restricted, repetitive behaviors were present but not in the degree that would warrant a more specific diagnosis. Childhood disintegrative disorder was described in the *DSM-IV* as differing from ASD in that it was marked by a period of developmental regression after at least 2 years of normal development. In the *DSM-5*, these 4 disorders were collapsed under the single heading of Autism Spectrum Disorder, as previous research found differential diagnosis between the categories to be unreliable. Furthermore, communication and social deficits were collapsed into a single category of possible deficits and children must meet the criteria for all 3 social/communication deficits to meet criteria for ASD. They must also exhibit at least 2 symptoms under the category of restricted, repetitive behaviors.

Additionally, the *DSM-5* now considers Rett syndrome to be a separate diagnosis from ASD because of its specific genetic etiology. Rett syndrome is associated with mutations of the *MECP2* gene on the X chromosome. It may be distinguished from ASDs in most cases by the loss of purposeful hand movements, gait abnormalities, development of specific stereotyped hand movements (hand wringing or mouthing), and severe to profound language and cognitive delays. It is predominantly expressed in girls, but a few cases in boys have been identified.

Publication of the *DSM-5* stimulated concerns that some children who previously would have met criteria in *DSM-IV* might now be excluded and not qualify for services. Studies have since demonstrated that most children who meet criteria for autistic disorder would now be diagnosed with ASD using *DSM-5*, although results have been mixed as to whether all those who would have been diagnosed with PDD-NOS or Asperger disorder under *DSM-IV* criteria would still be diagnosed with ASD under the *DSM-5* criteria. The *DSM-5* states that individuals diagnosed under *DSM-IV* criteria do not need to be rediagnosed, so these changes should not affect the services available to children who have already been diagnosed. Further study is necessary to assess the effect of the new classification system on children who have been evaluated for a possible ASD diagnosis since the *DSM-5* was published.

Autism spectrum disorder should be distinguished from a developmental language disorder. Language disorders are characterized by significant delays in receptive or expressive language skills (or both), but social interaction skills are not qualitatively impaired. It should be noted, however, that children with developmental language disorders may exhibit social deficits

because of their inability to maintain social interactions involving language. Other children and adults may unconsciously withdraw from a child who is not verbally responding, limiting the child's opportunities to develop social skills. Children with language disorders do not, however, usually demonstrate repetitive, restricted behavior patterns.

## EVALUATION

Diagnosing autism is not a straightforward process. No single biological marker, laboratory test, or procedure exists to identify children with autism. Although the diagnosis of autism is primarily a behavioral one based on a comprehensive history, direct observation, and standardized assessment, several medical procedures should be followed to rule out specific known causes of expressed behaviors. Guidelines for medical screening and diagnosis have been widely recognized by scientific and professional societies. The American Academy of Pediatrics (AAP) clinician fact sheet, *Initial Medical Evaluation of a Child Diagnosed With an Autism Spectrum Disorder*, provides an excellent overview of the diagnostic process for physicians.

Because of significant advances within the past 20 years in early behavioral and educational interventions for ASD, children clearly benefit from diagnosis as early as possible and referral to appropriate, effective intervention services. In accordance with this, the AAP recommends that primary care physicians screen for developmental concerns at every well-child preventive care visit. If concerns are raised, physicians should complete a standardized developmental screening test to determine if further evaluation is necessary. In addition, standardized screening tests for developmental delays should also be administered at the 9-, 18-, and 24- or 30-month visits. Specific to screening for ASD, the AAP guidelines recommend that an autism-specific tool should be administered to all children at the 18-month and 24- or 30-month visits. While the AAP recommends several standardized autism-specific tools, the Modified Checklist for Autism in Toddlers (M-CHAT) is one of the most widely used. Because the M-CHAT is designed to be an initial screener to identify the largest possible number of at-risk children, it has a high false-positive rate. The creators of the instrument developed a structured follow-up interview that physicians should use to better identify those in need of further evaluation.

## History

A comprehensive medical, developmental, and psychosocial history is the most important aspect of an evaluation for autism. An evaluator should document birth and neonatal history, developmental milestones, and any developmental regression. History that indicates delays in language and social development, excessive irritability, self-injury, feeding or sleeping problems, or any combination would support a diagnosis of autism, as would extreme hyperactivity, pica, or seizures. Family history of autism, ID, learning difficulties, language delays, mental health problems, and social difficulties should also be explored.

## Physical Examination

General physical examinations for children with suspected autism should consider several suggestive factors. Among children with autism, early childhood head circumference is sometimes larger than in typically developing children. Motor stereotypies of a nonfunctional character (eg, hand flapping) are the most common motor impairments in autism, although hypotonia and limb apraxia have been reported. The latter impairments are more common among children with isolated ID and other developmental disabilities than among children with autism. It is important to rule out hearing problems, as young children with hearing problems also often present with language delays and even some repetitive behavior (eg, shaking their heads back and forth).

*Tuberous sclerosis*, a neurocutaneous disorder affecting the brain and other organs, can account for 0.4% to 3% of children diagnosed with autism. Although 2 gene loci have been identified, the most common initial signs are ash leaf-shaped depigmented macules observed with exposure to ultraviolet light. Any child being assessed for autism should be exposed to ultraviolet light to exclude tuberous sclerosis. If the assessment is positive, the child should be referred to a geneticist.

## Laboratory Evaluation

Given the high rates of heritability in ASD and an increasing body of research that links the occurrence of ASD with epigenetic factors, it is recommended that a genetic consultation be completed with all children diagnosed with ASD (see Schaefer and Mendelsohn [2013] for more detailed guidelines on genetic consultation for patients with ASD). A microarray that tests developmentally significant regions of the genome and for common genetic syndromes, and a DNA study for fragile X syndrome should be offered to all families. It should be explained to families that although genetic testing will not change the treatment for specific ASD symptoms, results may provide an etiology for current symptoms, help the family better understand the risk of recurrence in siblings, and help identify other potential medical concerns associated with specific genetic syndromes. Metabolic and further genetic testing should be considered when additional physiologic signs (eg, unusual and dysmorphic features, seizures, abnormal growth) are observed, to rule out other possible syndromes associated with symptoms of ASD. Specific testing should be considered for:

- *PTEN* gene mutation when head circumference is greater than 2.5 standard deviations above the mean
- *MECP2* gene mutation to rule out Rett syndrome and related phenotypes when a child presents with microcephaly, deceleration of head growth, developmental regression, or the stereotypical "hand-wringing" movement associated with this syndrome. Although *MECP2* mutations are rare in males, further genetic testing should be pursued if these characteristic features are present
- Angelman syndrome when seizure disorder is present along with symptoms of ASD in early childhood,

as well as ID, overly happy affect, and repetitive hand waving/clapping

Electrophysiologic testing is necessary only in cases of suspected comorbid seizure disorder, severe sleep problems, or developmental regression.

### Imaging Studies

No imaging evaluation procedures are needed in a routine evaluation for autism. When other neurologic findings, such as seizure, asymmetric motor functioning, cranial nerve dysfunction, or severe headache, co-occur with suspected autism, the principles of standard clinical assessment apply.

## MANAGEMENT

The primary care physician's role in managing ASD begins with the careful screening of development during early childhood, and referral when needed for a specialist evaluation of developmental delays and unusual behaviors. After an accurate diagnosis of ASD is made, the physician's role is to provide ongoing care for the child within a medical home model of primary pediatric care, in accordance with AAP guidelines. More specifically, the pediatrician should strive to provide accessible, comprehensive, family-centered care for children with ASD, while evaluating for and helping manage common medical comorbidities, identifying the need for and perhaps managing psychopharmacologic interventions, coordinating specialty services and referrals, and advocating for effective psychosocial and behavioral interventions. Using a medical home model of care helps ensure that children receive needed preventive care and access to specialty services in a timely manner, and also helps avoid duplicating services by improving care coordination and communication between health care providers.

### Screening and Referral

Table 221-1 provides a description of some of the most common comorbid disorders and difficulties associated with ASD, along with considerations for screening and diagnosis, management, and referrals to specialty care.

### Psychopharmacology

To date there are no medications approved to treat the core symptoms of ASD (eg, social/communication deficits, restricted/repetitive behaviors), although there is evidence that behavioral problems commonly associated with ASD can be partially managed with medication. Medical providers must carefully weigh the possible benefits with the adverse effects commonly associated with these medications.

Symptoms of attention deficit/hyperactivity disorder (ADHD) are often seen in children with ASD, and the *DSM-5* now allows for both diagnoses to be given together. Physicians should carefully evaluate symptoms of hyperactivity, impulsivity, and inattention using current accepted standards of care to evaluate whether symptoms are significantly affecting functioning across environments (eg, school, home), ruling out other possible causes for these symptoms (eg, sleep problems, constipation/GI problems, anxiety/depression). If the child does meet the criteria for

comorbid ADHD, the physician should help the family connect with additional services (eg, school and mental health professionals) to set up appropriate behavioral and academic interventions. After appropriate interventions are put into place, the severity of the ADHD symptoms and effects on everyday functioning should be re-evaluated to determine if a trial of medication is necessary. Physicians should then follow the recommended guidelines for choosing an appropriate medication to begin treatment of ASD symptoms. Although stimulant medications (eg, methylphenidate and amphetamine preparations) are still most often prescribed as the first-line choice for treating comorbid ADHD, initial research has indicated that the rate of therapeutic response may be lower and the rate of side effects (particularly significant irritability) may be higher in children with both ASD and ADHD than in children with only a diagnosis of ADHD. Limited evidence suggests that atomoxetine and  $\alpha$ -2 agonists (eg, guanfacine and clonidine) may be effective in reducing ADHD symptoms, although research on effectiveness and side effects, particularly in an ASD population, is limited.

To date, risperidone and aripipazole, both atypical antipsychotic medications, are the only medications approved by the US Food and Drug Administration for treating behavioral problems in autism. While both of these medications have been shown to be effective in reducing irritability, aggression, self-injury, stereotypy, and hyperactivity in some children with ASD, they are also associated with several significant side effects including increased weight gain, sedation, and risk of extrapyramidal symptoms. Selective serotonin reuptake inhibitors (eg, fluoxetine, sertraline) have not been found to improve repetitive behaviors, and have been frequently associated with adverse effects in children with ASD. As of yet, no longitudinal studies have been completed that examine the long-term effects of any of these medications on the neurophysiologic development of young children. Further research on the effectiveness and long-term side effects of these medications in children with ASD is greatly needed to improve patient care.

### Advocating for Treatment

After an ASD diagnosis is made, primary care physicians are placed in the role of advocating for families to access the services and supports recommended by the developmental specialist. Helping families connect with the most effective treatment services while helping them avoid committing time, energy, and money to treatments with no known effectiveness is a difficult yet invaluable role.

The first step in advocating for effective treatment services is helping families access the support provided by state and local government agencies. If the child is younger than 3 years, a referral should be made to early intervention services. If the child is older than 3 years, a referral should be made to developmental disability services. What services are available and how these services are structured vary greatly from state to state. If families need further financial help, they can be advised to apply for social security benefits for their child.

**Table 221-1** Common Comorbid Disorders and Difficulties Associated With ASD

DESCRIPTION	CONCERNS RELATED TO SCREENING AND DIFFERENTIAL DIAGNOSIS	MANAGEMENT AND REFERRALS TO CONSIDER
<p><b>SEIZURE DISORDER<sup>a</sup></b> Estimated to occur in 7%–35% of children with ASD Peak risk periods for onset are in early childhood and in adolescence All types of seizures are seen but complex partial seizures are most common in ASD Most often seen with comorbid ID, dysmorphic features, and motor impairment</p> <p><b>SLEEP DISORDERS<sup>a</sup></b> Estimated to occur in 40%–80% of children with ASD Most common problems are with:</p> <ul style="list-style-type: none"> <li>• Sleep onset</li> <li>• Sleep maintenance</li> <li>• Sleep duration</li> </ul> <p>Children with ASD often have disrupted sleep patterns in which they wake during the night for periods up to 2–3 hours, during which time they may laugh, talk, or get up to play. Sleep problems in general tend to be more serious in children with ASD than typically developing children Sleep disturbance can lead to behavioral problems such as hyperactivity, inattention, or irritability</p> <p><b>GASTROINTESTINAL DISORDERS<sup>a</sup></b> Estimated to occur in 9%–70% of children with ASD Most common GI problems in children with ASD include:</p> <ul style="list-style-type: none"> <li>• Chronic constipation</li> <li>• Abdominal pain</li> <li>• Chronic diarrhea</li> <li>• Symptoms of GERD</li> <li>• Gastritis; esophagitis</li> <li>• Inflammatory bowel disease; celiac disease; Crohn disease; colitis</li> </ul>	<p>It can be difficult to distinguish between motor mannerisms and seizure activity Staring spells, cessation of activity, eye fluttering, eye deviations to one side, and behavioral changes such as confusion or fatigue may indicate concern for seizures It may be helpful to have parents take a video or keep a record of possible seizure activity to aid in differential diagnosis</p> <p>It is recommended that all children with ASD be screened for sleeping problems Possible screening tools:</p> <ul style="list-style-type: none"> <li>• Children's Sleep Habits Questionnaire (CSHQ)<sup>c,d</sup></li> <li>• Pediatric Sleep Questionnaire (PSQ)<sup>e,f</sup></li> </ul> <p>Rule out or address other problems that may be causing sleep disturbance</p> <ul style="list-style-type: none"> <li>• Obstructive apnea</li> <li>• Respiratory compromise secondary to enlarged tonsils and adenoids</li> <li>• Parasomnias</li> <li>• Side effects of medication</li> <li>• Anxiety/depression</li> <li>• GI disorders (eg, GERD)</li> <li>• Constipation</li> </ul> <p>A thorough medical history and physical evaluation, including nutritional assessment, should be completed Accurate evaluation of abdominal pain may be difficult given communication deficits In lower-functioning and nonverbal individuals, irritability, aggression, and self-injury may be signs of pain and discomfort</p>	<p><b>Referrals to consider:</b></p> <ul style="list-style-type: none"> <li>• EEG to evaluate seizure activity</li> <li>• Neurologist for further evaluation and medication management</li> </ul> <p>For further information see physician fact sheet and family handout in AAP toolkit<sup>b</sup></p> <p><b>Management:</b></p> <ul style="list-style-type: none"> <li>• Review appropriate sleep hygiene with families (eg, consistent bedtime routine, limit electronics 2 hours before bed, limit bedroom to sleeping). Family handouts available through AAP and ATN toolkits<sup>b,g</sup></li> <li>• May consider trial of melatonin, although it should be noted that rigorous efficacy studies have not yet been completed</li> </ul> <p><b>Referrals to consider:</b></p> <ul style="list-style-type: none"> <li>• Sleep specialist</li> <li>• Neurologist</li> <li>• ENT specialist</li> </ul> <p><b>Management:</b></p> <ul style="list-style-type: none"> <li>• Milder problems, such as constipation and GERD, may be managed in an outpatient setting following current recommended guidelines<sup>h</sup></li> </ul> <p><b>Referrals to consider:</b></p> <ul style="list-style-type: none"> <li>• GI specialist to evaluate and treat more serious/persistent problems</li> </ul> <p>For further information see physician fact sheet and family handout in AAP toolkit<sup>b</sup></p>

Effective psychosocial interventions for children with ASD have been developed, and early, intensive intervention is critical. Primary care physicians are placed in the role of advocate for a child's timely placement within highly intensive, behaviorally oriented intervention programs that are based on several decades of research. Nearly one-half of children with autism who receive at least 2 years of one-on-one behavioral instruction for 40 hours a week have been reported to achieve age-level functioning, including normal intelligence, average adaptive behavior, and regular educational placement. These findings have been partially replicated by other research groups, suggesting that early and intensive behavioral intervention can lead to improved cognitive and adaptive functioning outcomes for children with autism. This form of psychosocial intervention is known by many names, including applied behavior analysis, discrete trial training, intensive behavioral intervention, or early intensive behavioral intervention (EIBI). Early intensive behavioral intervention is the most descriptive of these terms and so will be used for the remainder of this section. This intervention typically occurs early (between the ages of 2 and 7 years), is intensive (20–40 hours per week), and is based on the principles of applied behavior analysis.

In an EIBI program, teaching methods and curricula are individually designed. This type of program consists of multiple teachers, sometimes called aides or therapists, working in 2- or 3-hour sessions, one-on-one with a child for up to 40 hours a week. Programs often last for several years, to ensure that children continue to make developmental progress. Each session includes structured, teacher-directed activities and free play. Early intensive behavioral intervention sessions are initially implemented within the child's home, but as treatment progresses, sessions are conducted in community and school settings. The child is taught new skills in a systematic, step-by-step fashion, and instruction is quickly paced, which helps keep the child engaged and interested. Teaching methods involve reinforcing children with favorite foods, preferred activities, and praise for successfully completing developmental tasks. The teachers help the children perform tasks that are initially too difficult for them using a system of prompts that are gradually phased out to promote an independent response. The curriculum used in EIBI programs is individually designed, hierarchically sequenced, and paced at each child's learning rate. The curriculum includes learning the prerequisites to language (eg, imitation, matching), expanding language and communication, play skills, self-help skills, and social skills, as well as early school-related concepts. Parents are also trained in the behavioral teaching methods and work to generalize the child's learning from the EIBI teaching sessions into everyday situations at home. The most successful children in EIBI programs are those who eventually discover how to learn from natural environments and typical educational experiences. Early intensive behavioral intervention has been recognized as an effective treatment by the US Surgeon General since 1999.

Many areas now offer school- or center-based EIBI programs for children with ASD that apply this teaching

method in a more traditional classroom model. Some special education departments in public schools are also adapting EIBI models to teach children with ASD and other developmental disabilities, although this dissemination process has been slow. While EIBI is often misperceived as a treatment modality only for very young or "low-functioning" children, this teaching method has been effectively incorporated into treatment models to teach social skills and other adaptive skills to children of all ages and functioning levels.

For families unable to access EIBI services or who plan to use a combination of EIBI and public education services, advocating for appropriate special education services in a public school setting is paramount. Families should be encouraged to have their child evaluated by their school to create an Individualized Education Plan (IEP) under the educational classification of autism. Understanding what services and supports are available to a child under the Individuals with Disabilities Education Act is difficult for any family. Physicians are encouraged to access or develop a short list of appropriate local and state advocacy resources for parents who are having difficulty accessing appropriate education services for their child.

Speech and occupational therapies are also indicated for most children with ASD. While many children will have these services provided to them through their IEP, it is also recommended that families access these services privately to maximize intervention time and to develop intervention plans that can be implemented specifically in the home environment. Older children with better language skills may also benefit from evidence-based social skills training focused on improving pragmatic language skills needed for effective communication and interaction with peers and adults. As children continue to develop, primary care physicians should begin to talk with families about plans for transition services once children graduate high school, including plans for health care, further education or vocational services, housing, guardianship, and financial management. These conversations should be started early so that a firm plan is in place by the time the child reaches 18 years.

Several commonly implemented interventions for ASD have emerging support of effectiveness (eg, TEACCH, Floortime), while others have been shown to be ineffective and even dangerous (eg, facilitated or supported communication, rapid prompting, auditory integration training, specialty diets, chelation, etc.). Medical providers should advise families to review carefully the evidence of effectiveness for any treatment before committing valuable resources.

## PROGNOSIS

The future has brightened for children diagnosed with autism over the past 20 or 30 years. Since the early 1990s, home childrearing and the availability of community special educational services for all developmentally disabled children has decreased the behavioral morbidities associated with institutionalization and restricted access to learning experiences. Parents and professionals have learned how to advocate effectively for these children, and these efforts

### BOX 221-1 Organizations Supporting Autism Research and Awareness

- Autism Speaks, Inc. Available at: [www.autismspeaks.org](http://www.autismspeaks.org). This organization and its Web site are dedicated to increasing public awareness about autism, providing advocacy, and supporting autism research. The Web site provides text and video segments to educate about autism.
- Cambridge Center for Behavioral Studies. Autism and Applied Behavior Analysis, Introduction to the Autism Section. Available at: [www.behavior.org/interest.php?id=2](http://www.behavior.org/interest.php?id=2). This organization, along with its Web site, provides resources and articles describing science-based information on effective autism treatment.
- Organization for Autism Research. Available at: [www.researchautism.org](http://www.researchautism.org). This organization, along with its Web site, is dedicated to promoting science in autism treatment. Several parent- or teacher-oriented publications on autism and Asperger disorder are available that can be downloaded free of charge, including the "Life Journey Through Autism" series.

have resulted in much wider adoption of empirically validated interventions in schools and health service settings. Intense study of ASD has become a federal research priority, and several private research advocacy groups have formed to support research and information dissemination efforts (see Box 221-1). Advances in epigenetics will likely shed light on the various causes of ASD and thereby provide prevention options.

### WHEN TO REFER

Children between 12 and 24 months of age should be referred to a developmental specialist if any one of the following exists:

- Delays in expressive communication: lack of babbling by 12 months, single words by 18 months, or phrases (not just echoed language) by 24 months
- An inability to follow simple instructions or imitate others by 12 months
- Little interest in social games by 12 months
- Little eye contact or social smiling by 12 months
- A lack of pointing out objects of interest by 18 months
- An inability to direct the child's attention or lack of response to name by 18 months
- No simple pretend play (eg, feeding a doll) by 18 months
- Little interest in other children by 24 months
- Loss of language or social skills at any age
- Repetitive motor movements or atypical body posturing (eg, hand flapping, body or facial tensing)

Children with a diagnosis of ASD may need to be referred for further evaluation and treatment for common comorbid conditions including:

- Seizures
- Sleep disorders
- GI concerns (eg, severe constipation, food allergies, malnutrition)
- Feeding difficulties
- Fine or gross motor delays
- Significant behavior problems (eg, aggression, self-injury, noncompliance)
- Mental health concerns (eg, significant anxiety or depression)

### WHEN TO ADMIT

- Severe malnutrition related to feeding difficulties
- Severe seizures
- Long-term electroencephalogram monitoring
- Life-threatening self-injurious behavior or aggression
- Psychopharmacologic toxicity
- Psychiatric stabilization

## Chapter 222

## BACTERIAL SKIN INFECTIONS

Kalyani Marathe, MD, MPH; Judith V. Williams, MD

Bacterial infections of the skin are common. They are most often caused by gram-positive bacteria, specifically *Staphylococcus aureus* and group A streptococci. The clinical disease that results depends on the infection's location within the skin. For example, impetigo involves only the most superficial layer of the epidermis; cellulitis is an infection deep in the dermis, even involving subcutaneous fat.

### IMPETIGO

#### Etiology

*S aureus* is the major cause of impetigo in childhood. It is responsible for virtually 100% of bullous impetigo and causes approximately 75% of nonbullous impetigo; the remainder is caused by group A  $\beta$ -hemolytic *Streptococcus* (GABHS). In developing nations and warm climates, GABHS is still more common than staphylococcus as a cause of impetigo.

In nonbullous impetigo, the skin lesions may start with small vesicles or pustules, but these are often not evident by the time the physician sees the patient. Crusts, usually honey colored, are seen instead. Removing these crusts exposes a moist, glistening base, which is a superficial erosion of the epidermis; culture usually reveals *S aureus*.

#### History

The patient usually has no history of preceding trauma to the skin. Mild to moderate itching may be associated with the lesions. Other family members also may be affected.

#### Physical Findings

Impetigo is found most commonly on the face and may appear as single or multiple lesions. Lesions may be scattered elsewhere on the body as well. The usual findings are yellow or honey-colored crusts, which when removed reveal a pink, superficially eroded, glistening base. The culture sample should be obtained from this base. With bullous impetigo, intact bullae, if present, contain deceptively clear fluid. These blisters break easily, leaving behind a superficially denuded skin surface covered with a thin, brown, varnish-like crust that is surrounded by a thin rim of loose, ragged epidermis, which represents the remnants of the blister roof (Figure 222-1). Surrounding erythema is minimal, and regional lymphadenopathy is rare.

**Figure 222-1** Bullous impetigo. The roof of the bulla is thin and delicate; the contents consist of some leukocytes that have settled at the inferior pole and some slightly turbid supernatant fluid. The larger adjacent bulla already has ruptured and discharged its contents. The delicate roof has collapsed onto the base. Lesions of this type may be caused by exfoliatin-producing organisms.

In bullous impetigo, the roof of the bulla is thin and delicate; the contents consist of some leukocytes that have settled at the inferior pole and some slightly turbid supernatant fluid. The larger adjacent bulla already has ruptured and discharged its contents. The delicate roof has collapsed onto the base. Lesions of this type may be caused by exfoliatin-producing organisms.

### Laboratory Evaluation

A Gram stain of either the clear blister fluid or the serum underlying the crusts shows gram-positive cocci. Cultures grow *S aureus* or *Streptococcus pyogenes*.

### Differential Diagnosis

Herpes simplex virus (HSV) infection is the condition most often confused with impetigo. Clinical clues that suggest herpes rather than impetigo are as follows:

1. Intact vesicles are more likely to be appreciated by both the patient and the physician in HSV infection than in impetigo. In HSV infection, as the vesicles age, they become cloudy and ultimately result in crusts that also may be honey colored. This crusted phase most often causes the diagnostic confusion.
2. HSV infection tends to be a recurrent condition, with the recurrences often in the same location (usually oral and perioral lesions). Such recurrence is not the case with impetigo.
3. When an impetiginous pustule is unroofed, it is noticeably filled with pus; a herpetic lesion may appear to be pus filled, but when it is unroofed, only a scant amount of clear fluid is found. In impetigo, Gram staining shows numerous gram-positive cocci. In HSV infection, Wright staining of a scraping from the base of a crust (or preferably a vesicle) reveals multinucleated giant cells.

### Exclusion From School

Given the potentially infectious nature of both staphylococcal and streptococcal skin infections, school nurses are appropriately concerned about this disease, and a child may be asked to leave school until the infection is treated. The period of infectiousness of impetigo is unknown. Most child care centers and schools recommend exclusion as long as open lesions persist. In reality, staphylococcal impetigo represents a rather low risk for spread in these settings; therefore, as long as lesions are covered, the child can return to school without posing a significant risk to other children.

### Management

Both topical and systemic antibiotics have been advocated for treating impetigo. Methicillin-resistant *S aureus* (MRSA) has become an increasingly common cause of skin infections in children. Several studies have indicated that up to 75% of community-associated *S aureus* skin infections in children are caused by MRSA, and 60% of community-onset health care-associated *S aureus* skin infections in children are caused by MRSA. Mupirocin topical antibiotic ointment has been reported to equal or exceed the efficacy of oral erythromycin in the treatment of bacterial impetigo and is recommended for initial treatment. A cream form is also available. The infected area should be washed carefully and the crusts gently removed, if possible, once a day, and the antibiotic cream or ointment is applied 3 times daily to the site. Traditional topical preparations that contain bacitracin or neomycin, either alone or in combination, have been used. However, because they are poorly absorbed, these preparations are not particularly effective. Topical mupirocin should be considered whenever feasible because it can be effective in treating impetigo caused by MRSA. However, mupirocin resistance is increasing in the MRSA USA 300 clone, the predominant circulating strain in the United States, and similar cases have been reported in different clones in other countries. Remarkably, mupirocin may retain the ability (albeit reduced) to decolonize patients with resistant strains. However, mupirocin is not effective in treating active infection with resistant strains. To optimize its efficacy, mupirocin should be used judiciously. Some authors recommend sampling MRSA populations for mupirocin susceptibility before incorporating mupirocin into infection-control programs and avoiding extended mupirocin use where MRSA is endemic. New topical preparations are in development. One such product, retapamulin, has some activity against MRSA in vitro, but clinical data are currently lacking.

Systemic antibiotics should be used for more extensive lesions. A study looking at medications most commonly prescribed for impetigo found that most physicians prescribe systemic antibiotics, even for uncomplicated infections. The traditional choices in the pre-MRSA era were erythromycin, a penicillinase-resistant penicillin (eg, dicloxacillin), amoxicillin-clavulanic acid, or cephalexin. These agents would still be appropriate for treatment of disease caused by methicillin-sensitive *S aureus* (MSSA) or *S pyogenes*.

Clindamycin or trimethoprim-sulfamethoxazole might be an appropriate choice in the era of MRSA, although one study about the treatment of skin and soft tissue infections found neither to confer benefit over penicillins. The treatment course should be 7 to 10 days. Patients with more extensive disease who fail traditional empirical antibiotic therapy should have cultures and susceptibility studies performed.

### Complications and Prognosis

With appropriate antibiotic therapy, prompt healing is expected; most patients show marked improvement within several days. Bacteriologic cures occur within 7 to 10 days in nearly all cases. If the infection does not respond rapidly to therapy, then it may be caused by an antibiotic-resistant strain. In such cases, the initial culture and susceptibility results serve as a guide in selecting an alternate antibiotic.

Historically, differentiating between staphylococcal and streptococcal impetigo was deemed important, given that glomerulonephritis can be a sequela of the latter form. Evidence now shows that treatment of streptococcal skin infections does not alter the risk for developing glomerulonephritis, but will prevent the cardiac complications of rheumatic fever.

## PYODERMA

### Etiology

In contrast to the superficial nature of impetigo, which mainly involves the top layers of the epidermis, pyoderma frequently extends through the epidermal layer into the underlying dermis. The process may start with small erythematous papules and rapidly proceed through vesicular, pustular, and crusted stages, during which stage it might be clinically confused with impetigo. Streptococcal pyoderma is more common in warm, humid environments; higher humidity favors the survival of group A streptococci on normal skin. Presumably, trauma to the skin results in inoculation followed by infection.

### History

Streptococcal pyoderma may occur in epidemics among children of lower socioeconomic status who live in crowded conditions in warm, humid environments. In contrast to impetigo the streptococcal skin lesions occur most commonly on the lower extremities, where they are usually preceded by trauma such as a scratch or insect bite. Family members also may be affected.

### Physical Findings

The early lesion is a pustule (hence the term *pyoderma*) with surrounding erythema, but the more advanced lesion of ecthyma is seen more often. At first glance, this lesion seems thick, usually brown crust surrounded by erythema. When the crust is removed, an actual ulcer is revealed (Figure 222-2), in contrast to the superficial erosion underlying the crust of impetigo. Also in contrast to impetigo, regional adenopathy is often present with streptococcal pyoderma.

In streptococcal pyoderma (ecthyma), lesions progress to become necrotic in appearance with deep

**Figure 222-2** Streptococcal pyoderma (ecthyma). Lesions progress to become necrotic in appearance with deep punched-out ulcers. The surrounding erythema and the location on the lower leg are typical of this streptococcal lesion.

punched-out ulcers. The surrounding erythema and the location on the lower leg are typical of this streptococcal lesion.

### Laboratory Evaluation

A culture sample taken from the base of the denuded ulcer usually grows GABHS. *S aureus* is occasionally recovered concomitantly, in which case it is thought to be a secondary invader.

### Differential Diagnosis

Ecthyma gangrenosum is an uncommon but serious manifestation of sepsis in immunocompromised hosts. It has been most frequently associated with *Pseudomonas aeruginosa* infection but can be seen with other gram-negative organisms or even with fungi. Clinical features that help differentiate this lesion from ecthyma are (1) the location (ecthyma gangrenosum is often on the upper extremities or in the inguinal or axillary folds), (2) the lesion's appearance (a deeper ulcer covered with a tightly adherent, black [gangrenous] crust), and (3) the host (a seriously ill, usually immunocompromised patient who exhibits other signs of sepsis).

### Management

Pyoderma is treated with antibiotics, although the most appropriate route of administration is still a matter of debate. Some evidence indicates that applying topical antibiotics to scratches and insect bites reduces the incidence of subsequent pyoderma; thus topical antibiotics may be advocated prophylactically for traumatic skin lesions. Although topical mupirocin has proved effective for impetigo caused by group A

streptococci, systemic antibiotics still are recommended for streptococcal infections, particularly if the infection is extensive. Injectable benzathine penicillin G is effective, but a 7- to 10-day course of oral penicillin or erythromycin is preferred if the patient is likely to be adherent to the prescribed regimen. Penicillin treatment occasionally fails, presumably because of the persistence of coexisting penicillinase-producing *S aureus* organisms. Even in the age of MRSA, penicillin should be the first-line therapy. Trimethoprim-sulfamethoxazole monotherapy has been shown to have higher failure rates than penicillins or clindamycin.

### Complications

Complications are uncommon, although both local and systemic problems can result from streptococcal pyoderma. Cellulitis may develop if the infection extends into larger and deeper areas of skin and subcutaneous tissue. Some strains of group A streptococci produce the toxin responsible for scarlet fever.

As mentioned previously, acute glomerulonephritis may follow streptococcal infection of the skin. It is caused by only a few nephritogenic serotypes (49, 55, and 57) of pyoderma-inducing streptococci. The usual period from onset of infection to development of the glomerulonephritis is 18 to 21 days. Fortunately, skin infection with streptococci never leads to acute rheumatic fever. Systemic antibiotic therapy clears the skin infection and helps to reduce the spread of streptococcal infection to the patient's playmates and family.

### Prognosis

The aforementioned complications are uncommon, and in most patients the lesions heal uneventfully. Because they are deeper, streptococcal lesions often take longer than staphylococcal lesions to heal; however, bacteriologic cures are usually accomplished within a week. If a prompt response is not achieved, then a secondary infection from a penicillinase-producing staphylococcal strain should be considered, particularly if penicillin was used for treatment. Erythromycin-resistant strains of group A streptococci also may be encountered.

## FOLLICULITIS

### Etiology

Bacterial folliculitis is a moderately common disorder that primarily affects older children and young adults. It is an infection of the hair follicles, caused almost exclusively by *S aureus*. In rare cases, the infection is caused by gram-negative organisms, which occurs occasionally in patients whose acne is being treated with antibiotics. Also, *P aeruginosa* is the usual cause of hot tub folliculitis, which causes pruritic papules and pustules on the trunk and proximal extremities. The lesions usually clear without treatment, although antipruritics can be used. Typically, however, *S aureus* causes folliculitis, and this type of infection is the subject of discussion here.

### History

Staphylococcal folliculitis appears most commonly as a chronic eruption unaccompanied by symptoms,

although occasionally a patient has mild discomfort or pruritus.

### Physical Findings

The lesions in staphylococcal folliculitis are usually located on the buttocks and upper portion of the thighs, over which individual small papules and pustules are scattered. The key to the diagnosis is that, on close inspection, hairs can be seen growing out of the very center of many of the lesions.

### Laboratory Evaluation

In the typical case, culturing is not usually necessary. If, however, the presentation is atypical and laboratory confirmation is desired, then the contents of a fresh pustule should be cultured.

### Differential Diagnosis

Clinically, folliculitis caused by gram-negative organisms differs from staphylococcal folliculitis in its distribution, with lesions occurring primarily on the face (often concentrated in the perioral and perinasal areas) and shoulders. Hot tub folliculitis usually appears on the lower trunk and areas most exposed to the contaminated water in the tub.

Keratosis pilaris is another common follicular disorder that exhibits as tiny, rough, scaling papules on the back of the upper parts of the arms, the buttocks, and the thighs. Although the distribution may be similar to that of staphylococcal folliculitis, the appearance of the lesions is not. In keratosis pilaris, the lesions are smaller, more numerous, and scaling, but not pustular.

### Management

The usual mild case of staphylococcal folliculitis can be managed by having the patient use an antiseptic cleanser (eg, chlorhexidine) or antibacterial soap containing triclosan or triclocarban daily or every other day for at least several weeks. Topical clindamycin lotion or solution applied twice a day may be a useful therapy. For more extensive involvement, a 7- to 10-day course of systemic antibiotics (eg, cephalexin or dicloxacillin) is suggested in addition to the topical regimen.

### Complications and Prognosis

Most patients respond to treatment; if not, then a bacterial culture should be performed to rule out infection by gram-negative organisms or MRSA. Some patients are plagued with recurrences, for which a more prolonged course of antibiotic therapy is recommended. In rare cases, the follicular infection extends deeply, producing a furuncle.

## FURUNCLES AND ABSCESES

### Etiology

Unchecked folliculitis may result in furuncles (pus-filled nodules or boils) that are almost always caused by *S aureus*. Although most physicians use the terms *furuncle* and *abscess* interchangeably, abscesses are collections of pus within the dermis and deeper skin tissues that do not originate from a primary folliculitis. Bacteria may be inoculated into the skin and underlying soft

tissue by traumatic injury, including surgery. Most skin abscesses are caused by *S aureus*, but gram-negative and anaerobic organisms also can be causes.

### History

A history of trauma may be elicited but often is not, especially with furuncles. Immunodeficiency states and diabetes may predispose certain patients to bacterial skin infections, but the typical patient who has a furuncle or abscess has no underlying medical disease.

### Physical Findings

Furuncles and abscesses are fluctuant masses filled with pus. They often begin as hard, tender, red nodules and become more fluctuant and painful with time. Abscesses tend to be larger and deeper than furuncles, but the 2 lesions may sometimes be difficult to differentiate clinically.

### Laboratory Evaluation

A Gram stain of the pustular material may provide a clue to the bacterial cause. However, for precise identification, cultures are required. If anaerobic cultures are desired, then material is ideally collected by aspirating the pus, sealing the syringe, and promptly delivering it to the laboratory. If insufficient material is available to aspirate, then a swab culture can be used for anaerobic, as well as aerobic, cultures. Blood culture results rarely are positive in patients with furuncles or abscesses and are not indicated unless the patient shows signs of sepsis.

Differentiation between an abscess and cellulitis can sometimes prove challenging. To avoid unnecessary incision and drainage procedures and ensure appropriate treatment, the use of ultrasound has gained popularity. An abscess classically has an anechoic or hypoechoic complex fluid collection, whereas cellulitis usually shows diffuse thickening, increased echogenicity of the skin and subcutaneous tissues, and hypoechoic strands traversing between the fat and connective tissue.

### Management

Very small furuncles can be treated with moist heat, which promotes drainage. For larger furuncles, incision and drainage are the mainstay of therapy. Clinical evidence suggests that, for furuncles less than 5 cm in diameter, incision and drainage alone result in complete healing in most cases. For patients with abscesses larger than 5 cm, or for those with surrounding cellulitis or signs of systemic illness such as fever, systemic antibiotics should be used. If lesions are seen early in their development, then systemic antibiotics may result in involution, obviating the need for incision and drainage. In the recent past, dicloxacillin, cephalexin, and erythromycin were considered the antibiotics of choice; however, this consideration needs to be re-evaluated in light of the increased incidence of MRSA in furunculosis. Pantón-Valentine leukocidin (PVL) factor-positive strains may be especially virulent; studies have shown that most strains causing furuncles are positive for PVL factor. Most community-associated MRSA isolates are susceptible

to trimethoprim-sulfamethoxazole, and many are sensitive to clindamycin. Clindamycin has the advantage of excellent penetration into the infected tissues; however, some erythromycin-resistant strains of MRSA have inducible resistance to clindamycin. The physician is advised to know local susceptibility patterns. Culture results from abscesses may help in the ultimate selection of the appropriate antibiotic.

### Complications

Recurrent furunculosis sometimes prompts a search for an underlying immunodeficiency, a search that almost always goes unrewarded. However, many such patients harbor *S aureus* in a sequestered mucocutaneous site, the most common of which is the anterior nares. Application of mupirocin to the external nares twice daily for 5 days, repeating the process monthly or every 2 months, decreases recurrences by approximately one-half. Some experts recommend an every-other-day total-body scrub with an antiseptic cleansing agent, such as chlorhexidine, or antibacterial soap containing triclosan or triclocarban, although overuse of these antiseptic soaps may dry the skin, harming skin integrity. Some physicians are also advocating the addition of a small amount of bleach to the bath water to reduce staphylococcal skin colonization.

Fritz et al found that a regimen of dilute bleach baths, intranasal mupirocin, and education effectively eradicated *S aureus* over a 4-month period better than topical antibiotics alone or in combination with chlorhexidine.

Most oral antibiotics do not eradicate nasal carriage of *S aureus*, but clindamycin is an exception. In cases that are refractory to all the previously described methods, a single oral dose of clindamycin, given twice daily for 7 days, may be effective at eliminating recurrences.

In rare cases, a staphylococcal abscess may be the focus of toxin production, resulting in staphylococcal scalded skin syndrome (most commonly seen in infants and neonates), toxic shock syndrome, or staphylococcal scarlet fever.

### Prognosis

Untreated lesions often rupture and drain spontaneously. After either surgical or spontaneous drainage, uneventful healing is the rule. Larger lesions may leave scars.

## CELLULITIS

### Etiology

Cellulitis is a deep, locally diffuse infection of the skin that has systemic manifestations and life-threatening potential. It usually involves the face, an extremity, or the perianal area. On an extremity, the bacteria presumably have been externally inoculated into the deep dermal tissue, although the portal of entry is often undetectable clinically. A hematogenous or lymphangitic source is also possible and may explain the development of cellulitis in some cases in which the overlying skin is unbroken. Before the introduction of protein-conjugated *Haemophilus influenzae* type b (Hib) vaccines in 1988, Hib was a

frequent cause of facial cellulitis (*buccal cellulitis*), usually accompanied by bacteremia, in children. The incidence of invasive infections from this organism in the United States has declined by 95% and now occurs primarily in undervaccinated populations or in infants who have not completed the primary Hib vaccine series. Almost 90% of cases of facial cellulitis in the post-Hib vaccine era are related to trauma or to dental or sinus infection. Buccal cellulitis is a disappearing disease.

Other organisms figure more prominently in cellulitis at other sites. Preseptal (periorbital) cellulitis is likely to be caused by *Streptococcus pneumoniae* in younger children and by group A streptococci in older children. *S aureus* and group A streptococci more commonly are responsible for cellulitis of the extremities. *S aureus* and group A streptococci are the most common causes of perianal dermatitis, with two-thirds of the latter patients also having positive pharyngeal cultures. In rare cases, other aerobic and anaerobic bacterial organisms, as well as deep fungal agents such as *Cryptococcus neoformans*, can cause cellulitis. These infections usually occur in immunosuppressed individuals.

### History

Children who have cellulitis often feel and seem ill. Fever is frequently present and may precede the clinical skin signs. Patients may complain of pain in the affected area. Symptoms of an accompanying otitis media may be present in buccal cellulitis. Patients who have perianal cellulitis often have pain on defecation. However, patients who have this infection are not usually systemically ill; thus, the disease may persist for weeks or months before it is correctly diagnosed.

### Physical Findings

Fever at the time of presentation is common. The area of involved skin shows the classic signs of inflammation: redness, swelling, heat, and tenderness.

### Laboratory Evaluation

Leukocytosis is a common finding. The causative pathogen is usually assumed from the history and physical examination, given that identifying it by culture is fraught with difficulty. Blood cultures are positive in less than 5% of cases. In neonates or undervaccinated hosts who have facial cellulitis, lumbar puncture with culture of cerebrospinal fluid may disclose unsuspected meningitis.

### Differential Diagnosis

Erysipelas is a form of cellulitis caused most commonly by group A streptococci. Because infection is limited to the upper dermis, erysipelas has raised and sharply demarcated borders. Bedside differentiation of erysipelas from cellulitis, however, is sometimes difficult and clinically not particularly useful because therapeutic considerations are generally the same for both conditions.

A severe, local, confluent contact dermatitis may sometimes be confused with cellulitis in that both may show marked erythema of the skin. The important differences are that with contact dermatitis, the patient complains of itch rather than pain, the skin

usually is not tender, and the patient is not febrile. The presence of vesicles also favors contact dermatitis, although vesicles and bullae may sometimes occur in erysipelas or cellulitis as the condition evolves.

Perianal dermatitis, originally thought to be a cellulitis but now known to be a more superficial infection, may be misdiagnosed as candidiasis or diaper dermatitis. Bright-pink erythema and pain or tenderness of the involved skin suggest bacterial infection, and a swab culture usually shows *S aureus* or group A streptococci. Laboratory personnel must be aware that they are to look for these organisms; otherwise, they will look for enteric flora with a culture from this site. Necrotizing fasciitis is a fulminant skin infection most often caused by group A streptococci (*flesh-eating bacteria*). It is characterized by warm, violaceous, exquisitely tender, and markedly edematous (orange peel-like) skin with indeterminate edges. Systemic toxicity with fever, leukocytosis, thrombocytopenia, hypocalcemia, and hyponatremia is often seen. Systemic antibiotics are an adjunct to prompt surgical debridement, which is the mainstay of therapy. Erythema of the cheeks occurs characteristically in erythema infectiosum (fifth disease, caused by parvovirus B19), in which a slapped-cheek appearance is noted. Important diagnostic differences between erythema infectiosum and cellulitis are that in the former, the involvement is bilateral, the site is not usually very tender, and the patient does not seem toxic, although the patient may be mildly febrile.

### Management

Systemic antibiotics are the mainstay of cellulitis therapy. Mild cases of cellulitis on an extremity may be treated with an oral antibiotic, warm soaks, and outpatient follow-up in several days. Because cellulitis of the extremity most often is caused by Gram-positive organisms, erythromycin, dicloxacillin, and cephalexin are appropriate drugs to use. More seriously ill patients, including infants and young children, patients with predisposing medical conditions such as diabetes mellitus, patients with immunodeficiencies or on immunosuppressive therapies, and those in whom sepsis is suspected, should be hospitalized for parenteral antibiotic therapy.

### Complications and Comorbid Conditions

In some instances, findings that are clinically diagnosed as cellulitis may actually be a clue to an underlying, deeper-seated infection. Cellulitis of the periorbital tissues may be secondary to sinusitis; abdominal wall cellulitis may hide an underlying peritonitis; redness, warmth, and swelling of tissues overlying bones or joints may indicate septic arthritis or osteomyelitis; facial cellulitis may be caused by an undiagnosed dental abscess; redness of the neck is sometimes a clue to underlying deep neck space infections; inflammation of the skin of the sacrum might be from an infected pilonidal cyst; redness of the pinna or postauricular area may point to malignant otitis externa or mastoiditis. Uncomplicated cellulitis was once a serious, life-threatening disease, but antibiotics have now reduced the fatality rate to nearly 0% in otherwise healthy patients.

### Prognosis

With appropriate antibiotic therapy, fever usually resolves within 24 hours. If it does not, then a change in antibiotic therapy should be considered, optimally guided by early culture and bacterial sensitivity results. The skin reaction resolves more slowly than does the fever, sometimes taking a week or longer to subside completely.

## COMMUNITY-ASSOCIATED METHICILLIN-RESISTANT STAPHYLOCOCCUS AUREUS INFECTIONS

The prevalence of community-associated MRSA is ever increasing. In fact, these strains cause most MRSA cases acquired in the community and are appearing in health care settings, traditionally the province of hospital-acquired strains. The most frequently reported presentation is furunculosis, followed by skin abscesses and cellulitis. Less frequently reported are bullous and nonbullous impetigo, nodules, pustules, and scalded skin syndrome. Community-associated MRSA strains are generally more susceptible to non- $\beta$ -lactam antibiotics (especially clindamycin and trimethoprim-sulfamethoxazole) than are nosocomial MRSA strains. However, some erythromycin-resistant strains develop resistance to clindamycin during treatment. The microbiology laboratory should provide results of a D-test for strains resistant to erythromycin; if the D-test is negative, then clindamycin can be used.

Community-associated MRSA is becoming a significant health concern, and studies are underway to find ways to reduce the spread of MRSA in families, schools, and communities.

### WHEN TO REFER

## Chapter 223

# BRAIN TUMORS

Sarah Rush, MD; Bruce H. Cohen, MD

The primary care physician (PCP) is often the first person to evaluate children with brain tumors; in one-half of children ultimately diagnosed with brain tumors, the diagnostic process was initiated by the PCP. Brain tumors, although rare, are the second most common cancer and the most common solid tumor in childhood. Therefore, PCPs should be mindful of the possibility of a brain tumor among the other potential explanations of a child's illness. A delay in making the diagnosis may ultimately affect the child's outcome. Some low-grade (previously referred to as benign) tumors can be cured with surgery. Many high-grade (previously referred to as malignant) brain tumors do not share the favorable prognosis of other common pediatric cancer diagnoses, and aside from a few exceptions, including medulloblastoma and nongerminomatous germ cell tumors, recent advances have only modestly improved outcomes. The prognosis depends on myriad factors, including tumor histology, molecular genetics, size, extent of dissemination, location, and age. Children who survive may experience substantial morbidity.

## DEFINITIONS

*Primary brain tumors* are tumors of the brain parenchyma, cranial nerves, meninges, and the pituitary gland and immediate surrounding structures. Brain tumors arise from a persistence of the embryologic precursors of neurons themselves (primitive neuroectodermal tumors [PNETs]), glial elements that provide structural and nutritional support to the neurons (astrocytomas and oligodendrogliomas), germ cell elements (germinoma and nongerminomatous germ cell tumors), the lining cells, such as the arachnoid (meningioma), the nerve sheath (schwannoma), the

pituitary gland (pituitary adenomas), or intracranial rests (craniopharyngiomas).

## INCIDENCE

In the United States, the incidence of primary brain and central nervous system (CNS) tumors is approximately 5.4 cases per 100,000 person-years, with an estimated 3,420 new cases to be diagnosed in the United States in 2015. The overall incidence is age-stratified, with the highest incidence occurring in the youngest children (0–4 years), with 5.8 cases per 100,000 person-years, and in the oldest children (15–19 years), with 5.91 cases per 100,000 person-years. Incidence is not affected by gender overall, but there is a slightly higher incidence of embryonal tumors and germ cell tumors in males. Reports suggest the incidence of childhood cancer, and particularly brain tumors, has been rising over the last 3 decades. The increase may be the result of improvements in diagnostic technology and reporting patterns, as well as possible environmental or other unexplained factors. For example, a substantial increase was observed after 1984 when magnetic resonance imaging (MRI) became widely available. While the incidence continued to rise, it stabilized from 2007 to 2011 with only a small decline in mortality associated with brain tumors. However, overall survival rates have improved over time, with 10-year survival rates of 56.3% (1982–1986), 65.4% (1992–1996), and 69.2% (2002–2006).

## RISK FACTORS

Only a few risk factors for brain tumors are universally accepted: previous therapeutic radiotherapy, predisposing genetic syndromes, and some aspects of maternal diet. Therapeutic low-intensity radiotherapy, such as that used in the 1950s for tinea capitis, is now linked to a long-term relative risk of meningiomas and malignant brain tumors as a result of total-dose of radiation exposure. Children who received therapy for acute lymphoblastic leukemia, including radiotherapy, are at increased risk for second malignant neoplasms, including CNS tumors.

Interestingly, children with primary CNS neoplasms without a documented genetic syndrome demonstrate an increased risk of a second CNS neoplasm. A 10-year cumulative incidence of 1.4%, regardless of previous therapy with radiotherapy or chemotherapy, has been reported. Inherited syndromes are also associated with a higher risk for childhood brain tumors, although they are only present in a minority of cases. These include neurofibromatosis types 1 and 2, tuberous sclerosis types 1 and 2, von Hippel-Landau syndrome, Li-Fraumeni syndrome, nevoid basal cell carcinoma syndrome, Turcot syndrome, ataxia-telangiectasia syndrome, Gardner syndrome, and Down syndrome. Certain aspects of maternal diet influence the risk of PNETs in young children, with strong protective dose-response relations observed for maternal consumption of fruit, vegetables, vitamin C, nitrate, and folate.

Other notable associations worth mentioning include pineoblastoma in children with retinoblastoma, pituitary tumors in children with various endocrine

adenomatosis syndromes, and the high incidence of pineal germinomas in Japan. Primary CNS lymphoma may be seen as a result of primary or secondary disorders of the immune system, as in acquired immunodeficiency syndrome, Wiskott-Aldrich syndrome, or ataxia-telangiectasia syndrome, and after solid organ transplantation.

## CLASSIFICATION

Brain tumors are classified according to their histology, but the location and extent of spread are important factors that affect treatment planning and prognosis. The most widely recognized classification system is the World Health Organization (WHO) classification of tumors, published in 2000, with more than 120 entries. This criteria system was established with the intention of encouraging and standardizing multicenter clinical trials. The system is designed to integrate histopathologic criteria with clinical, epidemiologic, radiologic, biologic, molecular genetic, and predictive factors and therefore continues to evolve, with new diagnoses continually being added.

The WHO classification recognizes 4 malignancy grades or estimates of malignant potential. However, the pathologic distinction between malignant and nonmalignant tumors may not always reflect the clinical course of the disease. Physicians now avoid using terms such as *benign* or *malignant* in favor of *low-grade* or *high-grade*, because the former terms can be misleading. Furthermore, the prognosis for some high-grade tumors is better than for some low-grade tumors. For example, an infiltrating low-grade glioma may have a less favorable long-term prognosis than a high-grade (malignant) PNET that is low-stage, completely resected, and treated with appropriate radiotherapy or chemotherapy. As another example, the craniopharyngioma has a benign histology, but if this tumor produces infiltration into the hypothalamic structures, then the course may be anything but benign. Finally, in some circumstances, such as infiltrating brainstem gliomas, the biopsy specimen may seem to be low-grade but the disease may still have an aggressive course.

## DELAY IN DIAGNOSIS

In contrast to many pediatric malignancies, especially leukemias, many weeks or months may pass for children with brain tumors between the onset of symptoms and diagnosis. Only one-third of children with brain tumors are diagnosed within the first month after the onset of signs or symptoms. The interval between the onset of symptoms and the time of diagnosis is approximately 9 weeks, including a parental delay of 5 weeks after noticing symptoms and a physician's delay of an additional 3 weeks. This time to diagnosis correlates with the child's age and the location and histologic type of the tumor. A shorter delay is common in infants, possibly because of closer supervision by their PCPs. Older children tend to have more subtle neurologic findings and are more likely to have a longer time from initial symptom onset to the definitive diagnosis.

## EVALUATION

### History

The manifestations of childhood brain tumors depend on the site of tumor origin, the child's age and developmental level, and whether accompanying hydrocephalus exists. No single clinical historical detail or physical finding is pathognomonic. Children will typically have a progression of symptoms and physical findings, which may not correlate with the grade of the underlying disease. Most children will have several suggestive features at the time of diagnosis; only 12% of children have just a single symptom. In infants, increased intracranial pressure (ICP) may exhibit insidiously with nonspecific signs such as drowsiness or lethargy, irritability, vomiting, abnormal tilting of the head, or developmental stagnation or regression. In older children, declining academic performance; fatigue; and emotional, appetite, or personality changes may occur before overt headaches and vomiting.

A well-studied symptom of brain tumor is headache. Headaches may be frontal, occipital, unilateral, or diffuse in location and may be exacerbated by Valsalva maneuvers, cough, or position. In most circumstances, headaches of more than 4 months duration, without neurologic features, are seldom caused by brain tumors. Other features that warrant further evaluation of a child with headache include the presence of a neurologic abnormality, ocular findings such as papilledema or decreased visual acuity, vomiting not otherwise explained by a viral illness, increase in frequency or severity of the headaches, recurrent morning headaches or pain that awakens the child from sleep, the presence of short stature or deceleration of linear growth, diabetes insipidus, age younger than three years, or a child with neurofibromatosis.

Vomiting is also an established symptom of childhood brain tumors and may be the result of increased ICP or, less commonly, direct irritation of the vagal nuclei on the floor of the fourth ventricle. Vomiting may be associated with morning or waking headaches and may also relieve the headaches.

In contrast to adults, seizures are not as frequently observed in children with brain tumors. However, aside from some well-characterized seizure syndromes, patients of any age who have seizures with a focal onset, either simple partial (focal) seizures or partial seizures with secondary generalization, should be evaluated for a tumor by MRI.

More specific symptoms may help localize the tumor. Infratentorial tumors commonly produce cerebellar symptoms such as clumsiness, worsening handwriting, scanning speech, or frank symptoms of ataxia and increased ICP. The infiltrating brainstem glioma may produce typical localizing signs of ataxia, cranial nerve symptoms (particularly diplopia because of sixth-nerve palsy), and long-tract signs (hemiparesis or tetraparesis), because this tumor invades the crossing cerebellar outflow tracks, brainstem nuclei, and the descending corticospinal tract. The nonlocalizing signs of this tumor can be headache and vomiting resulting from an obstruction of cerebrospinal fluid (CSF) flow and increased ICP.

Supratentorial tumors may result in symptoms specific to the location of the disease. Complaints of hemiparesis (muscle weakness) suggest the presence of disease in the cerebral hemispheres. Visual loss or visual field defects may be the result of disease localized anywhere along the optic tracts, and when associated with hormonal changes such as growth failure, diabetes insipidus, or precocious puberty, they imply the presence of tumors near the optic chiasm and hypothalamus. Tumors of the hypothalamus may also be associated with diencephalic syndrome in infants, which is characterized by failure to thrive, emaciation, and a euphoric mood.

### Physical Examination

In addition to a thorough history, a complete and thorough neurologic examination will reveal both localizing and nonlocalizing findings. These neurologic findings, with or without a complementary history, are required for further investigation and for referring the child to a specialist. Repeated neurologic examinations may be revealing because signs are often progressive in situations in which the diagnosis remains in question. Tumors may cause macrocephaly, generally seen when the tumor impairs the normal circulation of CSF, resulting in hydrocephalus. In an infant, this condition produces head circumference measurements that cross percentile lines on a standard chart. The findings of fontanel bulging, split cranial sutures, lack of upgaze, and alteration in tone are all indicative of hydrocephalus. Some infants will seem to be failing to thrive as a result of vomiting caused by the increased ICP. Papilledema is uncommon in infants because their skulls can expand, and the ICP does not increase enough to cause symptoms until much later in the course. In children with fused cranial sutures, hydrocephalus will result in increased ICP and cause papilledema. Focal or localizing signs can help identify the location of the tumor. Tumors of the cerebral hemisphere can result in personality changes, focal weakness, language dysfunction, visual field defects, or sensory changes. Tumors involving the visual pathway will obviously result in visual-field deficits. Pineal tumors and tumors involving the midbrain tectum cause *Parinaud syndrome*, a triad of paralysis of upward gaze with associated convergence-retraction nystagmus, lid retraction, and light-near dissociation of the pupils. If the tumor involves the midline structures of the cerebellum, then truncal ataxia will be the dominant sign. Tumors involving the brainstem can result in ataxia, corticospinal tract findings, and focal brainstem signs. Tumors involving the suprasellar and hypothalamic region may be associated with signs of an endocrine disturbance such as precocious or delayed puberty, growth failure, or constipation and dry skin indicative of hypothyroidism. The symptoms and signs of spinal cord tumors depend on the location of the tumor and its extent of infiltration into the surrounding tissue.

### Differential Diagnosis

Space-occupying lesions and causes of ICP are listed in Box 223-1.

**BOX 223-1 Differential Diagnosis**

- Arteriovenous malformations
- Subdural hematoma, effusion, or empyema
- Abscess
- Infarction
- Hemorrhage
- Demyelination
- Pseudotumor cerebri (Idiopathic intracranial hypertension)
- Hemiplegic migraine
- Todd paralysis
- Venous sinus thrombosis

**Laboratory Evaluation**

Patients with tumors of the pituitary gland and tumors that involve the pituitary stalk and hypothalamus should undergo evaluation of endocrine function before surgery. If the tumor involves the pituitary stalk or the posterior portion of the gland, then electrolytes and osmolality measurements can help diagnose diabetes insipidus. Children with midline supratentorial tumors should be evaluated for non-germinomatous germ cell tumors, such as choriocarcinoma, yolk-sac tumors, embryonal cell tumors, and the mixed variety. These tumors can excrete  $\alpha$ -fetoprotein,  $\beta$ -human chorionic gonadotrophin, and alkaline phosphatase. If present, these are most easily found in CSF, but they may also be detected in serum. Germinomas do not typically secrete these markers. Human immunodeficiency virus serologic testing may be useful if a diagnosis of primary CNS lymphoma is suspected, although this tumor rarely occurs in children.

**Imaging Studies**

Advances in neuroradiology have helped physicians make prompt and accurate diagnoses of childhood brain tumors. Computed tomography (CT) scanning is widely available, has short imaging times, and requires less sedation in young children, so it is often the first modality to be used. The initial CT scan can provide important immediate information about the presence of hydrocephalus, cerebral edema, midline shifts, and risk of uncal herniation. However, tumors of the brainstem, visual pathway, posterior fossa, and mesial temporal lobe structures may not be clearly visible.

Magnetic resonance imaging is the imaging modality of choice for the definitive diagnosis of CNS neoplasms. An MRI is more sensitive than a CT scan for most brain tumors and is the best imaging modality for tumors of the brainstem, posterior fossa, mesial temporal lobe, and spinal column. As with CT, a contrast agent will help detect many tumors because the gadolinium contrast agent accumulates in tissues that lack an intact blood-brain barrier. High-grade tumors infiltrate the surrounding tissues, inducing more surrounding edema and usually resulting in better contrast enhancement. In comparison, low-grade

gliomas, the most common childhood tumor, are well demarcated and generally have little surrounding edema.

**MANAGEMENT**

Treatment of most children with brain tumors requires a multidisciplinary team approach that includes pediatric subspecialists from the disciplines of neurosurgery, neurology, oncology, pathology, radiology, radiation oncology, endocrinology, and ophthalmology. In addition, these patients benefit from experienced pharmacologists; nurses; neuropsychologists; audiologists; nutritional experts; child life specialists; physical, occupational, and speech therapists; and social workers. The outcome of treatment for children with cancer has been shown to be better when care is provided at a specialized tertiary-care cancer center. In light of this circumstance, the American Academy of Pediatrics released a statement outlining guidelines for facilities, capabilities, and available personnel.

Children benefit from being treated with protocols developed by large cooperative cancer consortiums. Therefore, children should be considered for enrollment into a clinical trial whenever one is available. Clinical trials are carried out by single institutions in addition to collaborative groups such as the Children's Oncology Group and the Pediatric Brain Tumor Consortium.

The optimal therapy combination for most brain tumors is still being determined through clinical trials. However, the initial treatment of many brain tumors is often surgery. Presurgical corticosteroid therapy is essential for children with brain edema and increased ICP. Brain tumors contain tumor vessels that behave abnormally, favoring the formation of edema within and around the tumor as a result of the disruption of the blood-brain barrier. Methylprednisolone reduces capillary permeability in the tumor and adjacent brain tissue. Children treated with methylprednisolone often develop rapid and marked resolution of the edema with corresponding improvement of their symptoms and a more relaxed brain during the operative procedure. Other steroids with glucocorticosteroid effects, such as prednisone or dexamethasone, can be used as well.

Excision removes the tumor and resolves the surrounding edema. Neurosurgical techniques improved during the last 20 years, along with safer anesthesia and better intensive care management. The use of stereoscopic microscopes coupled with real-time surgical navigation systems is the most striking advance. A navigation system permits the operative burr hole to be placed with high precision; thus, allowing tumor resection through small openings. In addition, modern microscopes, coupled with surgical navigation, allow the surgeon to distinguish between healthy brain and tumor, resulting in a greater likelihood of total resection. Electrophysiologic monitoring during surgery also contributes to safer and bolder approaches. Intraoperative MRI has benefited select cases, but its widespread use is limited by its high cost and the often considerably longer operating times.

Although surgical resection is the goal for many tumors, some tumor types are best diagnosed by

neuroimaging or by histologic evaluation of biopsy material, when it can be obtained without substantial morbidity. Because of location, tumors situated in the deep gray matter, such as the thalamus and basal ganglia, are often biopsied by means of a stereotactic navigation system. Diffuse pontine gliomas and tectal plate gliomas are biopsied less frequently because of the risk of damaging essential structures and because they have a predictable histologic appearance and clinical course. The neuroimaging characteristics of visual pathway gliomas and intrinsic pontine gliomas are classic; therefore, pathologic corroboration of a diagnosis is seldom helpful. However, there is continuing debate over the need for more aggressive approaches for tumors in the deep, midline, or critical regions of the brain.

Most cerebellar and hemispheric low-grade gliomas are pilocytic astrocytomas. The strategy of choice for treating these children is gross total resection, which is often accomplished with the cerebellar forms of this tumor. For other tumors, debulking of the primary tumor allows for more effective chemotherapy and radiotherapy. Chemotherapy has improved the survival of many patients with CNS tumors, and radiotherapy is an important treatment modality for all but the youngest patients. In very young patients, new treatment protocols were developed involving intensive chemotherapy with stem cell rescue in an effort to replace radiotherapy and avoid its long-term consequences.

Current radiotherapies vary and include external-beam, 3-dimensional, and intensity-modulated radiotherapy, as well as stereotactic radiosurgery and gamma-knife surgery, which allow small-volume or local irradiation while sparing surrounding tissues and essential structures. Proton beam radiation is increasingly used to treat some pediatric CNS tumors. Long-term outcomes data are still needed to understand its role in pediatric radiation therapy. Radiation is the best therapy for many tumors, but it may result in growth failure, failure of intellectual and emotional development, and an increased risk for later development of malignancy caused by radiation exposure. For treatment decisions, especially in young children, one must consider the chance of cure and weigh it against the potential for profound morbidity and late effects.

The potential for further improvements in outcomes likely lies in collective clinical trials of new treatment strategies, including antiangiogenesis medications, monoclonal antibodies, immunotherapy, differentiation agents, anti-angiogenic agents, and gene therapy. Such trials are best conducted in collaboration with a network of experienced investigators working in specialized tertiary-care cancer centers.

### WHEN TO REFER

Children with a history that suggests brain tumor and children with focal findings at physical examination require further evaluation. Ordering a neuroimaging study is within the scope of practice for pediatricians and pediatric nurse practitioners and should be done emergently if the

symptoms and examination suggest a brain tumor or other intracranial pathology. Oncologists, neurologists, and neurosurgeons prefer early referrals, hoping that if the diagnosis of a neoplasm is made, then the tumor will be smaller and easier to resect, thereby causing less damage to adjacent brain tissue. New strategies to expedite and simplify referrals in other countries, including referral guidelines and cancer referral forms, have been used with good satisfaction rates, and adopting these strategies may be beneficial in local medical networks for streamlining the care of these children.

### WHEN TO ADMIT

Patients with signs of increasing ICP should be admitted urgently for evaluation and imaging. Computed tomography scanning can provide immediate information about ventricular size, the volume of the normal cisternal spaces, shifting of normal brain structures, and degree of ICP. Progressive life-threatening symptoms may include increasing blood pressure and decreasing heart rate, sixth-nerve palsy, or occipital headaches caused by irritation of posterior roots of the cervical cord. These symptoms may quickly progress to neck stiffness and eventually opisthotonus, a spasm of the body in which the head and heels are bent backward and the body is bowed forward. In addition, children with supratentorial mass lesions may exhibit pupillary dilatation, often unilateral initially, from uncal herniation. This manifestation may culminate in tonsillar herniation, which is also a potential sequela of an untreated posterior fossa mass lesion, obstructive hydrocephalus, or both. In all these clinical situations, a neurosurgeon should be consulted urgently.

## Chapter 224

# BRONCHIOLITIS

Caroline Breese Hall, MD<sup>†</sup>

**DEFINITION**

Bronchiolitis is a common, acute viral lower respiratory tract illness of children occurring during the first 2 years of life. It is the number one cause of hospitalizations for infants in the United States. Furthermore, the number of bronchiolitis admissions has increased in recent years among infants in the United States and Canada. This has resulted in an appreciable and escalating economic burden to our health care system.

The clinical picture of bronchiolitis has been described since the beginning of the 20th century, but the disease was associated with a variety of sobriquets, including wheezy or asthmatic bronchitis, acute

<sup>†</sup>Deceased

catarrhal bronchitis, and spastic bronchopneumonia. The syndrome was not recognized as a separate entity until Engle and Newns gave it distinction by designating the infantile disease as bronchiolitis.

Although *bronchiolitis* means inflammation of the small airways, the bronchioles, it is usually defined by its clinical and epidemiologic manifestations. The American Academy of Pediatrics (AAP) characterizes bronchiolitis as “a constellation of clinical symptoms and signs including a viral upper respiratory prodrome followed by increased respiratory effort and wheezing in children less than 2 years of age.” Bronchiolitis may be further defined to include only children within the first year of life with an initial episode of wheezing. This definition emphasizes bronchiolitis as an acute lower respiratory tract disease with wheezing, which distinguishes it from the recurrent wheezing among older children that is frequently associated with upper respiratory tract infections, such as the rhinoviruses. The consensus definition of bronchiolitis from the United Kingdom, which also is based on the epidemiologic and acute clinical manifestations, is “a seasonal viral illness characterised by fever, nasal discharge, and dry wheezy cough. On examination there are fine inspiratory crackles and/or high pitched expiratory wheeze.”

**ETIOLOGY**

Although initially bacteria were thought to be the cause of bronchiolitis, respiratory viruses, primarily respiratory syncytial virus (RSV), the parainfluenza viruses, and human metapneumovirus (hMPV), are now recognized as the major agents of bronchiolitis (Table 224-1). RSV is the most frequently identified cause of bronchiolitis and the one most commonly identified as the sole agent. RSV has been estimated to

**Table 224-1** Causes of Bronchiolitis by Season

VIRUS	FREQUENCY OF DETECTION IN BRONCHIOLITIS	SEASONAL OCCURRENCE
Respiratory syncytial virus	++++	Major outbreaks annually Fall to spring
Human metapneumovirus	++	Annual, fall to spring
Parainfluenza virus type 1	+	Fall, every other year
Parainfluenza virus type 2	+	Sporadic, mostly fall, winter
Parainfluenza virus type 3	++	Yearly, spring into fall
Influenza A or B	+	Late fall to spring Onset, strains, prevalence vary yearly
Rhinoviruses	+ - ++	Endemic
Enteroviruses	+	Summer to fall Prevalence, type vary yearly
Human coronaviruses NL63, HKU1, 229E, OC43	+	All year; Geographic variation
Adenoviruses	+	Endemic

cause 50% to 85% of bronchiolitis cases. The relative roles of other viruses have been variably reported depending on the methods and population. The determination of the agent causing the acute manifestations also is confounded by the frequency of viral infections that occur in young children and by the occurrence of coinfections in as many as 30% of young children with respiratory symptoms. Many agents infecting infants have prolonged and asymptomatic shedding, such as bocaviruses, adenoviruses, and picornaviruses (enteroviruses and rhinoviruses). Rhinoviruses are frequently detected among young children with acute respiratory illness, especially of the upper respiratory tract. Although rhinoviruses are well associated with reactive airway disease, their role in bronchiolitis and lower respiratory tract disease in infants is less clear.

The frequency of hMPV as a cause of bronchiolitis has been variably reported, but it appears to contribute an appreciable proportion of bronchiolitis cases. The course and epidemiology associated with hMPV infection are similar to those of RSV, but hMPV is acquired at a slightly older average age and more slowly. All the parainfluenza viruses may cause bronchiolitis, but the major one is parainfluenza virus type 3, which causes primary infection and bronchiolitis in the first year of life. Influenza A and B are important causes of acute respiratory illness in young children and of hospitalizations among infants. However, the proportion of influenza infections in young children that manifest as bronchiolitis is relatively small. The role and importance of the non-severe acute respiratory syndrome (SARS) human coronaviruses, such as HCoV-NL63 and HCoV-HKU1, detected in young children with respiratory illnesses continues to be defined.

### EPIDEMIOLOGIC CHARACTERISTICS

The seasonal pattern of bronchiolitis is well determined in temperate climates and reflects the activities of its viral agents, particularly RSV (Figure 224-1).

Yearly outbreaks of bronchiolitis occur during the winter to spring when RSV is epidemic in the community (Figure 224-2). Lesser peaks are observed during the fall, when the parainfluenza viruses are present in the community, and during the spring, concurrent with the major activity of parainfluenza virus type 3.

Bronchiolitis occurs primarily in children within the first 2 years of life, and more than 80% of bronchiolitis cases occur during the first year of life. The peak attack rate among hospitalized children is less than 6 months of age, whereas among children cared for in pediatric practices, the highest attack rate is observed in the second 6 months of life.

The rates of hospitalization for bronchiolitis estimated in 1996 from national databases were 31.2

**Figure 224-1** Seasonal occurrence of bronchiolitis cases obtained over a 26-year period from a community surveillance program in Monroe County, New York.

**Figure 224-2** Seasonal pattern of major respiratory viruses; respiratory syncytial viruses; parainfluenza viruses types 1, 2, and 3; influenza viruses; human metapneumoviruses; picornaviruses; and adenoviruses. Data from laboratory-confirmed surveillance in Monroe County, New York.

per 1000 children younger than 1 year of age and 2.3 per 1000 children 1 to 4 years of age. However, the rates of hospitalization for bronchiolitis among infants enrolled in a Tennessee Medicaid program were estimated as 71 per 1000 infants, and the rates estimated for the emergency department and outpatient visits were 77 and 238 per 1000 infants, respectively. In addition, 19% to 40% of bronchiolitis visits to emergency departments have been reported as resulting in hospital admission. Recent population-based studies in the United States have estimated RSV-associated hospitalization rates, 85% of which were bronchiolitis, to be 17 per 1000 children younger than 6 months of age and 5 per 1000 children 6 to 12 months of age each year. These rates are more than 3 times the rates associated with the parainfluenza viruses or with influenza among the same population. The rates of outpatient visits for bronchiolitis or RSV are less well studied but seem to be much greater, 10 to 20 times higher, than the rates for hospitalized patients.

Multiple anatomic, genetic, and environmental factors have been associated with an increased risk for more severe bronchiolitis (Figure 224-3). Boys are about 1.5 times more likely to develop bronchiolitis

than girls. Anatomic and physiologic differences between boys and girls, such as airway tone, may partly explain the male preponderance. Among the socioeconomic and environmental factors that have been correlated with a greater likelihood of developing bronchiolitis are lower socioeconomic status, exposure to tobacco smoke, lack of breastfeeding, contact with other young children (including having one or more siblings), and child care attendance. Most important, however, are young age, particularly within the first several months, and the presence of underlying conditions that affect cardiopulmonary function with and without chronic lung disease.

## DIFFERENTIAL DIAGNOSIS

Several conditions with wheezing and respiratory distress in young children may seem similar to bronchiolitis. Asthma is the major consideration in the differential diagnosis of bronchiolitis. Often in a single episode, differentiating these 2 entities is not possible. Wheezing associated with both bronchiolitis and asthma in young children is engendered by viral infections. Differentiation is further confounded by the possibility that a link exists between them, with RSV infection in infancy leading to subsequent wheezing episodes associated with asthma. Nevertheless, previous episodes of wheezing and a family history of atopy are more suggestive of asthma than of bronchiolitis.

Another diagnostic consideration is gastroesophageal reflux, which in the infant may exhibit primarily episodes of wheezing and may produce a picture clinically identical to that of bronchiolitis. However, history of the timing in relation to feeding and frequency of the wheezing episodes, as well as the lack of upper respiratory tract signs typical of a viral infection, are helpful in differentiating gastroesophageal reflux from bronchiolitis.

Other entities that may result in wheezing and respiratory distress in the age group of children with bronchiolitis that should be considered include obstruction from an aspirated foreign body, a vascular ring, retropharyngeal abscess, and, rarely, significantly enlarged adenoids. Wheezing also may occur in congestive heart failure and in chronic lung disease, such as that associated with prematurity and cystic fibrosis.

## EVALUATION

### History

A carefully obtained history of wheezing in a child is integral in both determining the diagnosis and assessing the potential for developing severe or complicated illness. The diagnosis of bronchiolitis is usually based on the clinical history and physical findings. Features that strongly support the diagnosis include the illness occurring during a community outbreak of one of the major viral agents, mainly RSV; young age (especially <12 months); and no prior episode of wheezing. The risk factors, as noted in Epidemiologic Characteristics, for the development of more severe disease need to be assessed, especially the presence of prematurity,

**Figure 224-3** Factors that contribute to severity of viral bronchiolitis. (Reprinted with permission from Hall CB, McBride J. Bronchiolitis. In: Mandell J, Bennett J, Dolin R, eds. Principles and Practice of Infectious Diseases. 7th ed. New York, NY: Churchill Livingstone; 2009:885–890.)

cardiopulmonary disease, immunodeficiency, and other underlying diseases.

The infant with bronchiolitis typically has a recent history of signs compatible with a common cold: rhinorrhea, nasal congestion, a low-grade fever, and cough. As infection spreads to the lower respiratory tract, the cough becomes more prominent, followed by tachypnea. Fever is commonly present during the prodromal period but is usually not high. By the time bronchiolitis associated with RSV develops, only about 50% of children are febrile.

### **Clinical Manifestations and Pathogenesis of Physical Findings**

On physical examination, an increased respiratory rate is almost always evident. Whether a child is tachypneic must be judged based on age. The overall respiratory rate in full-term newborns is about 50 breaths per minute but decreases over the first year of life to a mean of about 40 per minute at 6 months and a mean of 30 per minute at 1 year of age. Tachycardia commonly accompanies the tachypnea. The infant may appear irritable, lethargic, or anxious. Flaring of the nasal alae and expiratory grunting signify an increased work of breathing. Retractions of the chest wall in the subcostal, intercostal, and suprasternal areas and use of the accessory muscles of respiration also may be evident.

Respiratory distress arises from the inflammation of the respiratory epithelium of the upper and lower respiratory tract and obstruction of the medium and small bronchi and bronchioles. The viral infection causes increased mucus production, edema, and necrosis of the bronchiolar epithelium, which is sloughed into the lumen of the small airways. Because resistance to the flow of air is related inversely to the radius of the lumen, the small diameter of the bronchioles makes the infant particularly vulnerable to obstruction caused by the edema and inflammatory exudate.

Peripheral to the sites of partial obstruction, air becomes trapped by a process similar to a ball-valve mechanism. During inspiration, the negative intrapleural pressure allows air to flow past the site of partial obstruction. On expiration, however, the positive intrathoracic pressure decreases the diameter of the bronchiolar lumen, causing an increase in the degree of obstruction, and hyperinflation of the lung ensues. If the inflammation progresses, complete obstruction can occur, and when the trapped air is absorbed, multiple areas of focal atelectasis result.

This characteristic hyperinflation is evidenced on the physical examination by an increased diameter rounding the chest and hyperresonance on percussion. The liver and spleen may become easily palpable from the downward placement of the overinflated lungs. The airway obstruction is further reflected by a prolonged expiration that may be difficult to detect in a young infant who has a rapid respiratory rate. The flow of air also is impeded on inspiration but to a lesser extent. Auscultation usually reveals wheezing with or without crackles, but these findings may vary from hour to hour. Indeed, fluctuating physical findings on examination is characteristic of bronchiolitis in infants. However, a decrease in the auscultatory findings

accompanied by increasing respiratory distress may indicate progressive obstruction to the flow of air in the small airways and impending respiratory failure.

Additional clinical findings may develop from acute complications during the infant's course. Apnea is an infrequent but potentially fatal acute complication of bronchiolitis and RSV infections among infants, and it may be the first manifestation of the respiratory illness. Most at risk for apnea are infants of premature gestation and those whose postconceptional age is less than 44 weeks. The subsequent prognosis for children with apnea associated with RSV infection is generally good and does not appear to be associated with an increased risk for subsequent apnea, even during subsequent viral infections. Otitis media is also present in 3% to 30% of infants and may be caused by the infecting virus, bacteria, or both. The risk for dehydration complicating the course of infants with bronchiolitis arises from paroxysms of coughing that trigger vomiting and by the decreased fluid intake resulting from congested nasal passages and from the respiratory distress. In addition, tachypnea and fever may increase fluid requirements. Aspiration has been noted to occur frequently among infants hospitalized with RSV bronchiolitis and has been correlated with an increased risk for subsequently developing hyperreactive airway disease. This risk, however, has been shown to be abrogated by the prophylactic administration of thickened feeds for the prevention of aspiration.

### **Clinical Course**

Most infants who have bronchiolitis improve appreciably within several days, and the cough and other respiratory signs resolve gradually thereafter over 1 to 2 weeks. Most hospitalized children are discharged within a few days, often 2 to 3 days. Radiographic resolution of atelectasis, however, may require several weeks. Among ambulatory children, the median duration of illness has been reported to be 12 days for those younger than 24 months. However, 18% remained symptomatic after 3 weeks and 9% after 4 weeks. The clinical course tends to be more prolonged in young infants, those with underlying conditions, and those who acquired the infection nosocomially. Whether simultaneous infection with more than 1 virus in children with bronchiolitis results in more severe clinical disease is unclear. Although 1 small study reported an increased risk for requiring assisted ventilation among children who were coinfecting with RSV and hMPV infection, other studies have not found a greater severity of infection when more than 1 virus is detected.

### **Laboratory Testing**

Laboratory diagnostic tests for healthy infants with their first episode of wheezing are not routinely recommended because the diagnosis of bronchiolitis is usually based on the history and clinical findings. Unless the child's course is atypical or abruptly changes, diagnostic tests such as the complete blood cell count, measurement of arterial oxygen saturation, serum chemistries, and cultures to detect bacterial infection are generally not helpful or necessary for the management of previously normal children who have not had

prior wheezing. Furthermore, limiting diagnostic testing has been associated with benefits in both cost and clinical outcomes.

Pulse oximetry, which is a common part of the evaluation of children with bronchiolitis, has been demonstrated not to improve the outcome for infants with bronchiolitis, and its use has been associated with a lower threshold for hospitalization, higher rates of admission to intensive care units, and mechanical ventilation.

Tests for viral identification also are not routinely recommended because most children respond to supportive care alone. Assays to identify the specific virus may be warranted for selected and more severely ill children in whom specific antiviral therapy for RSV or influenza is being considered. Specific viral testing may also be beneficial in determining feasible infection control procedures, such as cohorting.

The laboratory tests most commonly used to determine the viral causes of bronchiolitis are rapid antigen detection assays because of their ease, cost, and rapid results. Rapid antigen detection assays are available for most of the respiratory viruses commonly causing bronchiolitis, including RSV, the parainfluenza viruses, influenza viruses, and hMPV, and assays for many additional viruses have been developed and are becoming more widely available. The sensitivity and specificity of these rapid antigen assays vary, and the positive predictive value significantly diminishes when the prevalence of the viral agent is low in the community. Thus, these assays preferably should be used during periods of peak activity. Reverse-transcriptase polymerase chain reaction (RT-PCR) and other molecular diagnostic assays are highly sensitive and specific for the diagnosis of multiple viral agents. Because of their sensitivity, infecting agents may be detected over prolonged periods, leading to confusion about which agent is the cause of the acute illness. Quantitative PCR assays may help in some instances. Viral isolation techniques are rarely used because of their variability, the technical expertise required, their cost, and the fact that some agents of bronchiolitis cannot be readily isolated in cell culture. Recent increased use of RT-PCR has consistently demonstrated these assays to be significantly more sensitive than viral isolation.

Antibody determinations on acute and convalescent sera in the young infant are rarely helpful in clinical management because of the time required to obtain a convalescent serum, the presence of passive maternal antibody, and the diminished antibody response of young infants to some viral respiratory agents that cause bronchiolitis.

### Imaging

Imaging should not be used routinely in the previously healthy child in whom the diagnosis of bronchiolitis can be made based on clinical and historical findings. In a prospective study of children 2 to 23 months of age being evaluated in an emergency department, routine chest roentgenograms provided little benefit. Less than 1% identified findings consistent with bronchiolitis. Furthermore, chest roentgenograms led to greater use of unwarranted antibiotics. Radiographic evaluation, therefore, should be reserved for those patients in

whom the diagnosis of bronchiolitis is not clear and the course is not as expected. Chest roentgenograms also should not be used to monitor the course of an infant with bronchiolitis or to decide admission or discharge. Importantly, the findings on the chest roentgenograms commonly are relatively benign and do not correlate with the severity of illness. The characteristic findings associated with bronchiolitis are increased bronchovascular markings radiating out from the hila and scattered small areas of atelectasis. The observed areas of atelectasis may be mistakenly interpreted as areas of pneumonic infiltration and of bacterial infection. Prospective studies have shown that the outcome and duration of illness among children with suspected lower respiratory tract infections who were evaluated with chest roentgenograms were not improved.

### MANAGEMENT

Management of most infants who have bronchiolitis, whether they are outpatients or hospitalized, consists primarily of supportive care, including adequate rest, comfort, hydration, and antipyretics, if necessary. Congestion of the nasal passages and upper airway, which may contribute to an infant's work of breathing, may be alleviated by gentle nasal suctioning and positioning of the infant. Mist therapy has not been shown to be beneficial. Chest physiotherapy, including percussion and vibratory techniques, have been of no clinical value and are not recommended. For the more severely affected child who is hospitalized, the need for supplemental oxygen administration should be judged by repetitive readings indicating an inadequate oxygen saturation level. Consensus does not exist on the level of oxygen saturation that indicates the need for supplemental oxygen, but the recent AAP bronchiolitis guidelines recommend initiating supplemental oxygen when the oxyhemoglobin saturation is persistently less than 90% and considering discontinuation of the supplemental oxygen when the level is persistently at or above 90%.

Beyond these measures, little agreement exists within the United States or among other countries about the value and use of therapeutic modalities. Although evidence is lacking that shows benefit for most of the commonly used therapies, especially for those who are first-time wheezers, corticosteroids, antivirals, antibiotics, and especially bronchodilators are frequently administered.

Studies evaluating the use of bronchodilating agents in bronchiolitis have given variable and contrasting results. Most controlled trials and reviews of the use of  $\beta$ -adrenergic agents have not shown consistent clinical benefit in children hospitalized with their first episode of wheezing. Among outpatient children, some studies have suggested transient or short-term clinical benefit when evaluated by varying clinical score systems. The AAP recommends that bronchodilators should not be used routinely in the management of bronchiolitis but that a carefully monitored trial of inhaled  $\alpha$ - or  $\beta$ -adrenergic agents is an option. However, the bronchodilator should be continued only if a beneficial clinical response is clearly documented.

Corticosteroid medications are frequently administered to infants with bronchiolitis. In some facilities,

most infants with bronchiolitis are treated with systemic glucocorticosteroids. However, meta-analyses have not shown consistent or statistically significant benefit, and the AAP recommends that therapy with corticosteroid medications should not be used routinely for the care of infants with a first episode of bronchiolitis. A large multicenter double-blind randomized trial evaluating the administration of corticosteroids to children with bronchiolitis was conducted in 20 emergency departments in the United States and completed in 2006. Children 2 to 12 months of age with a first episode of wheezing from moderate to severe bronchiolitis received a single dose of oral dexamethasone (1 mg/kg) or placebo over 3 respiratory seasons. No significant difference between the 2 groups was observed in the requirement for hospitalization. The same lack of benefit of corticosteroid therapy was observed in the subgroups of children with asthma or with a family history of asthma. A multicenter study from the Pediatric Emergency Research Canada Network subsequently confirmed the lack of benefit from corticosteroid administration. The network of emergency departments evaluated 600 previously well infants presenting with their first episode of bronchiolitis treated with a 6-day course of dexamethasone and also found no significant clinical benefit compared with placebo, even among infants who received corticosteroids along with nebulized epinephrine.

Antivirals that are potentially useful for viral agents that cause bronchiolitis are few. Inhaled ribavirin, a synthetic nucleoside, which has in vitro antiviral effect against a wide spectrum of respiratory viruses, is the only agent currently approved for the treatment of RSV lower respiratory tract disease in infants. Ribavirin is not recommended routinely to treat children with bronchiolitis and generally should only be considered for use in infants with conditions that place them at high risk for developing severe disease. The drug is expensive and difficult to administer to ventilated patients, and the benefits in clinical outcome are controversial. Its use therefore should be decided on an individual basis after consideration of its relative clinical benefit to its cost in the child's management. Antivirals for influenza have not been approved as therapy for young infants or evaluated in the management of bronchiolitis. Antibiotics should not be used unless a bacterial infection is documented or evidence strongly indicates the concurrent presence of a bacterial infection, which is uncommon in bronchiolitis and RSV lower respiratory tract disease.

## PROGNOSIS

Despite the recent increasing number of hospitalizations for bronchiolitis, the mortality associated with bronchiolitis and RSV has declined. The mortality among children younger than 5 years associated with bronchiolitis between 1979 and 1997 was estimated by the Centers for Disease Control and Prevention to be an average 95 cases, with a range of 66 to 127 cases each year for all children younger than 5 years and highest in those younger than 1 year. Deaths in infants associated with RSV infection more recently have been estimated to be less than 400 per year.

The most frequent sequela of bronchiolitis, especially that caused by RSV, is recurrent wheezing, which is reported to occur in 30% to 50% of the children who had a history of hospitalization for bronchiolitis. Episodes of recurrent wheezing tend to occur most frequently during the first 2 years after the initial episode of bronchiolitis. Most of these children subsequently improve and become symptom free. However, lung function abnormalities may persist beyond 10 years, despite the clinical improvement. Significantly reduced mean expiratory flow rates and an increased risk for bronchial hyperreactivity during adolescence have been demonstrated.

Other follow-up studies, however, have shown that these children, when reaching school age, have no greater risk for hyperreactive airway disease than children with no history of bronchiolitis. One episode of bronchiolitis and less severe bronchiolitis not requiring hospitalization also have not been associated with later pulmonary abnormalities. The relationship between bronchiolitis in early infancy and the subsequent development of hyperreactive airway disease is unclear and confounded by the increasing recognition that asthma or hyperreactive airway disease is a heterogeneous group of disorders with variable pathogenesis.

### WHEN TO REFER

- When episodes of bronchiolitis or wheezing are recurrent or started at birth
- When wheezing continues despite clinical improvement

### WHEN TO ADMIT

- When oral intake is inadequate
- When the child appears toxic or has marked tachypnea or lethargy
- When respiratory distress is rapidly progressive
- When history suggests apneic episodes

**Chapter 225****CANCERS IN CHILDHOOD**

Lisa Hackney, MD; Jennifer Greene Welch, MD;  
Cindy L. Schwartz, MD, MPH

Advances in the treatment of solid tumors of childhood during the past 20 years have ensured the long-term survival of approximately three-fourths of children with these diagnoses. The pediatrician who discovers a solid tumor may not—and need not—know the best treatment available. However, early referral of such a child to the appropriate specialist, a pediatric oncologist, greatly affects the likelihood and the quality of survival. Whenever possible, children with solid tumors should be offered enrollment on clinical trials to treat their cancer, such as those offered through the Children's Oncology Group (COG) cooperative mechanism.

Initial evaluation by the primary care pediatrician appropriately involves evaluation of acute symptoms, careful physical examination, consideration of personal and family history predisposing to malignancy, preliminary imaging studies, and rapid referral to a pediatric oncologist. Many common tumors are unique in children. For all solid tumors in children, therapies must be designed to minimize effects on growth and development. Appropriate use of the therapeutic modalities (surgery, chemotherapy, and radiation) provides maximal efficacy and minimal toxicity

of therapy. Early integration of palliative care for most children diagnosed with cancer also aids in management regardless of the overall prognosis because therapy for cancer includes significant effect on quality of life.

The child and parents should be encouraged to plan for the future. Educational and developmental needs must be addressed by the pediatric team, with the generalist and specialist working together. Such a team is also able to address the needs of the child, the parents, and the siblings if treatment is not successful. Fortunately, most children are cured and will return to the pediatrician for many years of general pediatric care.

This chapter describes the following solid tumors seen in children: Wilms tumor, neuroblastoma, retinoblastoma, rhabdomyosarcoma, germ cell tumors and teratomas, Ewing sarcoma, osteosarcoma, non-Hodgkin lymphoma, and Hodgkin disease. The role of the pediatrician in the care of these children is also examined.

**WILMS TUMOR**

Wilms tumor, or nephroblastoma, is a malignant renal tumor of childhood that occurs at an annual rate of approximately 8 per 1 million children in the United States. It is the second most common abdominal tumor of childhood. Wilms tumor comprises 5% to 6% of pediatric cancers. This number translates to approximately 600 to 700 new cases diagnosed each year in the United States. Children are usually between 2 and 5 years of age. Only rarely does the tumor occur in teenagers and adults. Bilateral disease occurs more commonly in younger children and in girls. The presence of bilateral disease should prompt consideration of genetics evaluation for inherited syndromes or germline mutations. It is one of the few pediatric malignancies that occurs more often in black children than in white children.

The chemosensitivity and radiosensitivity of this tumor, in conjunction with the ability to resect most nonmetastatic tumors, have allowed a multidisciplinary approach to be highly successful. Wilms tumor has become the model for treatment of childhood cancer. Over the last 4 decades, the National Wilms Tumor Study (NWTs) and the COG have evaluated successive therapeutic regimens, with the goal of increasing the cure rate and decreasing the duration and toxicity of therapy. The cooperative group approach has made possible the gathering of more data than might have been obtained at single institutions. The findings, such as the superiority of multiagent chemotherapy and the importance of tumor histology, are relevant for many tumors.

**Etiology**

Most Wilms tumors occur sporadically. Wilms tumor also occurs at increased frequency in siblings, cousins, and parent-child pairs, particularly in association with specific congenital anomalies and bilateral disease. Genetic counseling for patients with these family history risk factors is appropriate. Of children who have Wilms tumor, 15% to 20% have a genetic predisposition to the disease; however, a much lower incidence

of Wilms tumor in children who have affected relatives has been reported (approximately 1% to 2%).

Congenital anomalies occur in 13% to 28% of children with Wilms tumor, although most children who have the disease do not have anomalies. Most of the reported anomalies involve the genitourinary tract. Hemihypertrophy is second in frequency, sometimes noted as a component of the Beckwith-Wiedemann syndrome (excessive growth of many body organs). Children with isolated hemihypertrophy also have an increased incidence of Wilms tumor. Of children who have the sporadic form of congenital aniridia, 33% will develop Wilms tumor. WAGR syndrome is the association of Wilms tumor, aniridia, genitourinary abnormalities, and intellectual disability. Denys-Drash syndrome represents the association of Wilms tumor with ambiguous genitalia and diffuse glomerular disease. Both WAGR syndrome and Denys-Drash syndrome are associated with germline mutations of the *WT1* gene, located at 11p13. *WT1* abnormalities have also been identified in a small subset of patients, 6% to 10%, who have apparently sporadic Wilms tumor, usually in association with genitourinary anomalies. Mutations in *WT1*, *WTX*, and *CTNIB1* underlie the genetic basis of about one-third of Wilms tumors. A Wilms tumor suppressor locus may be at 11p15, which is also the locus for the familial form of Beckwith-Wiedemann syndrome. Genetics consultation may assist in the evaluation of these genetic syndromes.

Loss of heterozygosity at 1p and 16q has also been identified in Wilms tumors, and NWTs/COG demonstrated a worse prognosis for children with tumor-specific loss of heterozygosity at these chromosome regions. *WT1* mutations and 11p15 loss of heterozygosity are associated with relapse in children with very low-risk Wilms tumor who do not receive chemotherapy. In fact, ongoing clinical trials use these mutations as

biomarkers to facilitate risk stratification for patients. Further investigation of chromosomal abnormalities and genetic markers in Wilms tumor and other malignancies will provide insight into tumorigenesis and potential new directions for therapy.

Screening for Wilms tumor by ultrasound and urinalysis in patients who have aniridia, WAGR syndrome, Denys-Drash syndrome, isolated hemihyperplasia, or Beckwith-Wiedemann syndrome is recommended every 3 months until age 7 years. Screening may also be appropriate for children who have unexplained nephropathy and who have other multiple congenital anomaly syndromes and for siblings of children with bilateral Wilms tumor.

### Clinical Manifestations

Wilms tumor in children is usually characterized as a painless mass discovered by a relative, often during bathing. The mass usually is firm, occasionally lobulated, and confined to 1 side of the abdomen. Rapid abdominal enlargement, anemia, and hypotension (perhaps because of a sudden subcapsular hemorrhage) are occasionally present when the child seeks care. Hypertension, malaise, abdominal pain, hematuria, and fever each occur in 20% to 30% of patients. Hypertension has been attributed to hyperreninemia. Wilms tumor tends to extend locally through the venous system as well as to spread hematogenously to lungs, liver, and, rarely, brain or bone.

Table 225-1 presents the differential diagnosis of abdominal and pelvic tumors of childhood that may mimic Wilms tumor.

### Evaluation

The evaluation of a child with possible Wilms tumor begins with a history and physical examination. Particular attention should be paid to the associated

**Table 225-1**

**Differential Diagnosis of Abdominal and Pelvic Tumors in Infants and Children**

TUMOR <sup>a</sup>	AGE	CLINICAL SIGNS	LABORATORY FINDINGS
Wilms	Preschool	Unilateral flank mass, aniridia, hemihypertrophy	Hematuria
Neuroblastoma	Preschool	GI or GU obstruction, raccoon eyes, myoclonus-opsoclonus, diarrhea, skin nodules (infants)	Increased VMA, increased HVA, increased ferritin, stippled calcification in mass
Non-Hodgkin lymphoma	>1 yr	Intussusception in >2 yr old	Increased urate
Rhabdomyosarcoma	All	GI or GU obstruction, sarcoma botryoides, vaginal bleeding, paratesticular mass	—
Germ cell or teratoma	Preschool, teens	Girls: abdominal pain, vaginal bleeding Boys: testicular mass, new-onset hydrocele	Increased hCG, increased AFP
Hepatoblastoma	Birth to 3 yr	Sacroccygeal mass or dimple	Increased AFP
Hepatoma	School age, teens	Large, firm liver Large, firm liver; hepatitis B, cirrhosis	Increased AFP

AFP, Alpha-fetoprotein; GI, gastrointestinal; GU, genitourinary; hCG, human chorionic gonadotropin; HVA, homovanillic acid; VMA, vanillylmandelic acid.

<sup>a</sup>Other causes: constipation, splenomegaly, hydronephrosis, kidney cyst, full bladder.

congenital anomalies and the family history. Laboratory studies should include a complete blood cell count, urinalysis, and renal and liver function tests. Bleeding within the tumor may cause anemia. An erythropoietin-secreting Wilms tumor may cause polycythemia. Hypercalcemia may occur in children who have congenital mesoblastic nephroma or a rhabdoid tumor of the kidney.

A plain-film radiograph of the abdomen may show coarse calcifications, unlike the fine, stippled pattern commonly seen in neuroblastoma. Mass effect may be noted on the film. Ultrasonography is often performed first; this modality is particularly helpful in evaluating the renal vein, vena cava, and the right side of the heart for tumor spread. An abdominal computed tomography (CT) scan or magnetic resonance imaging (MRI) with contrast may reveal an intrarenal mass displacing and distorting the collecting system of the involved kidney. The tumor may be very large, and minimal kidney parenchyma may be identified. Six percent of children will have bilateral disease, and in 12% multifocal involvement in a single kidney may be recognized. Liver metastases may be diagnosed by ultrasound, CT scan, or MRI. Magnetic resonance imaging may be used to define the extent of the abdominal tumor to minimize diagnostic radiation exposure over the long term. A chest radiograph may demonstrate pulmonary nodules. A CT scan of the chest to detect small pulmonary metastases should be performed before surgery because postoperative atelectasis can obscure the presence of metastatic nodules. Bone scans are indicated in children who are ultimately diagnosed with clear cell sarcoma of the kidney, which often spreads to bone. At the time of surgery, the tumor is staged, as outlined in Box 225-1.

Wilms tumors are pathologically designated as being of either favorable histology (FH) or unfavorable histology (UH). Favorable histology indicates the absence of unfavorable features. Unfavorable histology involves the presence of anaplasia, defined by

the presence of gigantic polypoid nuclei within the tumor sample. Anaplasia may be focal or diffuse. Anaplasia conveys a worse prognosis, diffuse more than focal, which seems to be caused by resistance to chemotherapy and radiotherapy and not to biologically more aggressive disease. Anaplasia is present in 5% of patients, is more frequent in older children than younger children, and is more common in black children than children in other ethnic groups. Two other renal tumors—clear cell sarcoma of the kidney and rhabdoid tumor of the kidney—were previously considered Wilms tumor variants, but they are now considered as separate entities. In the COG, they are treated specifically as high-risk renal tumors.

### Management

Currently, in the United States, the initial therapeutic approach is complete resection by nephrectomy. This approach requires meticulous and gentle surgical techniques to prevent the tumor from spilling. A large transabdominal incision facilitates full exploration and excision. The entire ureter is removed, and lymph nodes are sampled. Previously, the practice was to examine the contralateral kidney and abdominal cavity for evidence of disease. However, this approach may not be required with current radiologic techniques; tumors too small to be identified on CT can be expected to be treated adequately with chemotherapy. Tumors deemed unresectable by clinical and radiologic evaluation are biopsied initially, with second-look resection performed after adequate chemotherapy-induced shrinkage is achieved.

For bilateral disease, chemotherapy is initiated based on imaging findings alone; older approaches of performing bilateral biopsy or immediate resection of the most involved site as was done in previous years are now discouraged because of risk for intra-abdominal seeding. Second-look excision of residual disease may be accomplished by partial nephrectomies, when possible. Patients with underlying syndromes, such as WAGR syndrome, should be considered for partial nephrectomies similar to patients with bilateral disease because of the high risk for renal failure. Because the risk for renal failure is only 0.25% to 0.6% in children with sporadic disease, the higher surgical and recurrence risk does not currently justify routine use of partial nephrectomies in this population, although it may be considered in certain children.

Most patients receive postoperative chemotherapy, and patients with higher stages of disease undergo radiation therapy. Actinomycin D and vincristine were noted to be effective systemic agents in the mid-1960s. The initial study revealed that radiotherapy in combination with a single agent (actinomycin D or vincristine) provided approximately 55% relapse-free survival in children with localized disease. An 81% relapse-free survival rate was found when both agents were administered in conjunction with radiation. These 2 drugs are now the mainstay of chemotherapy for Wilms tumor. Subsequent studies have demonstrated that radiotherapy is not necessary for low-stage tumors. The addition of doxorubicin as well as low-dose (10 Gy) radiation to vincristine and actinomycin D improved the prognosis for children who had stage III or IV FH

#### BOX 225-1 Staging of Wilms Tumor

- Stage I: Tumor is limited to the kidney and is completely resected. Renal capsule is intact.
- Stage II: Tumor extends beyond the kidney, but is completely resected.
- Stage III: Residual non-hematogenously spread tumor confined to the abdomen, including abdominal-pelvic lymph node involvement, peritoneal contamination before or during surgery, peritoneal implants, or any residual tumor postoperatively. Unresectable tumors, those biopsied only, and those treated with preoperative chemotherapy are also stage III.
- Stage IV: Hematogenous metastases are present. Sites include lung (only site in 80% of patients who have metastases), liver, distant lymph node, and, less commonly, bone, brain, and other sites.
- Stage V: Indicates bilateral renal involvement is present, although for treatment purposes each kidney is staged independently (I through III as above).

tumors, as well as for those who had stages II to IV tumors with focal anaplasia. Cyclophosphamide, carboplatin, and etoposide are added to vincristine, actinomycin D, and doxorubicin for children who have stages II to IV tumors with diffuse anaplasia and other high-risk histology. Current COG protocols risk-stratify patients based on loss of heterozygosity (LOH) at 1p and 16q, with patients found to have LOH receiving additional chemotherapy. Some children with very low risk disease, young children with small, FH, stage I tumors, may be treated with surgical resection only. Local tumor rupture is treated with low-dose flank irradiation. Peritoneal seeding or major tumor rupture necessitates radiation of the entire abdomen. In the United States, radiation is used for pulmonary metastases visible on CT that do not resolve with initial chemotherapy and for other hematogenous metastases.

Future directions for therapy include further risk stratification strategies to allow titration of treatment to optimize cure and minimize late toxicity. The role of initial surgery versus preoperative chemotherapy as used in Europe, the role of pulmonary radiation based on imaging and response to chemotherapy, and the role of first-line doxorubicin therapy are also areas for continued study.

### Prognosis

The prognosis of children who have Wilms tumor is determined primarily by the histopathologic factors of the tumor; that is, more patients with UH tumors die compared with children with FH tumors. Unfavorable histology tumors, particularly diffuse anaplasia, continue to confer a worse prognosis. More intensive regimens continue to be studied for patients with UH features.

Prognosis also depends on the stage of disease at diagnosis and LOH. Most relapses occur within 2 years of diagnosis. Two-year relapse-free survival for stages I to III disease with FH findings is approximately 91%. The 2-year relapse-free survival rate is 84% for children who have stage IV disease and FH features. Children who have diffuse anaplasia have a poor prognosis, with only 59% with stage II, 45% with stage III, and 7% with stage IV disease surviving 4 years after diagnosis. Four-year event-free survival is 74.9% for children with focal anaplasia. Children who experience relapse have a better prognosis if their initial management did not include radiotherapy or doxorubicin. Autologous transplantation procedures are being investigated in children with high-risk, relapsed disease. Future therapy will focus on improving the outcome in children with UH tumors, incorporating prognostic tumor chromosomal analyses into treatment assignments, and limiting treatment for those with positive prognostic factors.

### Follow-up

Children are monitored for disease recurrence at the primary site, usually with abdominal ultrasound alternating with CT or MRI of the abdomen, and in the lungs, usually with chest radiography alternating with chest CT. Some children may be followed up with CT of the chest and abdomen. Such monitoring continues

at increasing intervals until approximately 5 years after diagnosis. Long-term survival is likely in children who have Wilms tumor. Virtually all patients have had a nephrectomy. Contact sports are often discouraged, although evidence for a significant risk for renal injury is lacking. Some experts suggest a kidney guard for particularly active children, if only to serve as a reminder of the need for caution. In addition, patients should have their renal function and blood pressure monitored.

Children should be monitored for specific late effects of chemotherapy depending on agent and cumulative dose received. Consensus guidelines for monitoring survivors of childhood cancer are available from COG. Children treated with doxorubicin need to have cardiac monitoring, although current cumulative doses of anthracycline for most children with Wilms tumors should not place them at significant risk for cardiomyopathy. Children treated with cyclophosphamide and etoposide need to be monitored for secondary malignancy.

Scoliosis was a major problem for early survivors treated with moderate-dose radiation (30 to 40 Gy), particularly if the entire vertebrae was not included in the field, because of impaired growth of the irradiated portion of the vertebrae. The use of lower-dose radiation (10 Gy) and irradiation of the entire width of the vertebrae adjacent to the renal bed have decreased the severity, but has not entirely prevented the development, of scoliosis. Alterations of vertebral growth and tethering caused by hypoplasia of soft tissues may still result in some degree of curvature. Close observation of children who received irradiation, particularly during the growth spurt during puberty, remains necessary. Hypoplasia with a decrease in adipose tissue occurs in the radiation field and is accentuated by obesity; therefore, prevention of obesity minimizes this asymmetry.

Fertility is preserved in most females who have Wilms tumor, although a risk for ovarian failure exists with whole-abdomen radiotherapy. The average size of infants born to female survivors of irradiation is smaller than that of nonirradiated women, and increased miscarriages and premature births in female survivors of Wilms tumor who received radiotherapy have been reported. In addition, some of these patients may have underlying uterine anomalies. Continued follow-up of these offspring is necessary to evaluate the genetic factors involved in the occurrence of Wilms tumor.

## NEUROBLASTOMA

Neuroblastoma is a cancer, primarily of early childhood, that arises from the fetal neural cells that normally develop into the sympathetic nervous system. It is a tumor that provides insight into the biologic processes of malignancy. There is a spectrum of clinical phenotypes ranging from tumors in infants, which often demonstrate spontaneous regression or maturation into benign ganglioneuromas, to children older than 1 year of age who have disseminated disease. These children with metastatic disease remain difficult to cure despite aggressive use of multimodal therapy.

Neuroblastoma is the most common extracranial solid tumor in children and is the most common malignancy of infants, accounting for more than one-half of cancers in infants. Neuroblastoma accounts for 7% of all diagnosed cases of cancer in children and for 15% of childhood cancer mortality. Approximately 9.7 white children and 7.4 black children per million in the United States are diagnosed with neuroblastoma each year—about 800 to 900 new cases. Ninety percent of children who have neuroblastoma are younger than 5 years of age, and 97% are diagnosed before the age of 10 years.

### Etiology

The high incidence of neuroblastoma in early infancy suggests that its development may be related to abnormal maturation of fetal neural crest cells. The finding of microscopic nodules of adrenal neuroblastoma in infants younger than 3 months of age who died of unrelated causes suggests that spontaneous maturation or regression occurs in many children.

Families have been reported in which neuroblastoma occurred in multiple siblings or occasionally in multiple generations. A family history of neuroblastoma is found in about 1% to 2% of newly diagnosed cases. The presentation of familial neuroblastoma differs from sporadic disease in that children are diagnosed at an early age and with multiple primary tumors. The *ALK* gene has been identified as a major familial neuroblastoma predisposition gene. Familial neuroblastoma is also rarely associated with Ondine's curse (congenital central hypoventilation syndrome) with germline mutation of the *PHOX2B* gene. Some researchers have proposed that 20% to 25% of neuroblastomas occur in children who have a prezygotic germline mutation. Neuroblastoma has been reported to occur with an increased incidence in children who have Hirschsprung disease. The genetic bases for these familial and Hirschsprung-related cases are being elucidated. Although reported in other syndromes, no clear increased frequency has been determined. Recent studies have demonstrated that diet, particularly folic acid intake, and breastfeeding may protect against the development of neuroblastoma.

### Clinical Manifestations

Neuroblastoma may arise anywhere along the sympathetic nervous system chain, including the adrenal gland (40%), the paraspinal regions of the abdomen (25%), the thorax (15%), the neck (5%), and the pelvis at the organ of Zuckerkandl (5%). The incidence of primary site varies by age, with thoracic and cervical tumors more common in infants. The presenting features largely depend on the location of the tumor. A large, firm, irregular abdominal mass that may cross the midline is often the first sign of disease. Disturbances of bowel or bladder function may be the result of compression by a pelvic mass. Thoracic masses may cause a persistent cough or respiratory distress and are detected by a chest radiograph. Cervical masses are often initially diagnosed as lymphadenitis, but they do not respond to antibiotic therapy. Either

Horner syndrome or heterochromia iridis suggest the possibility of neuroblastoma.

Neuroblastomas that arise in the paravertebral ganglia tend to grow into the intervertebral foramina, forming a dumbbell-shaped mass. Pain, weakness of an extremity, paralysis, or incontinence may result from spinal cord compression by the intraspinal component. Incontinence may be difficult to assess, however, because many patients will still be in diapers. Cord compression is an oncologic emergency that requires surgical decompression, radiation, or chemotherapy to prevent permanent paraplegia. Studies have shown that long-term functional outcome may be better in children treated with chemotherapy compared with laminectomy.

Approximately one-half of the children who have neuroblastoma have metastatic disease at the time of diagnosis. The symptoms may then be related to the metastatic tumor instead of the primary tumor. Infants may have metastatic hepatic involvement. Rapid liver enlargement can cause marked abdominal distention followed by respiratory compromise. Bluish skin nodules, which may release catecholamines if palpated, are sometimes noted in infants who have neuroblastoma. Palpation causes an erythematous cutaneous flush, lasting for 2 to 3 minutes, and is followed by blanching caused by vasoconstriction.

The 2 most common sites for metastases are bone marrow and bone; other common sites include lymph nodes, liver, and intracranial and orbital sites. Disease in the lung and central nervous system (CNS) is uncommon. Infiltration of the bone marrow may cause pancytopenia. Bone involvement may produce pain, with or without palpable bone masses. Lytic bone lesions are found most often in the skull, orbit, or proximal long bones. A raccoon-like appearance caused by proptosis and eyelid ecchymosis has been described in children who have orbital involvement. Intracranial disease usually results from meningeal metastases. In infants, this disease may show as separation of cranial sutures caused by increased intracranial pressure. Infants and children who have neuroblastoma may also have fever, malaise, and failure to thrive. Secretory products of the tumor may be the cause of intractable diarrhea, which may be a presenting sign of neuroblastoma. Vasoactive intestinal polypeptide has been found in 7% to 9% of children who have neural crest tumors, most frequently ganglioneuromas or ganglioneuroblastomas.

An unusual symptom of neuroblastoma is the syndrome of opsoclonus-myoclonus. These children have acute cerebellar ataxia and rapid, dancing-eye movements. Although these children often have localized disease and usually are cured, residual neurologic dysfunction, including residual ataxia and intellectual disability, is common. The etiology of this syndrome is unclear, although it may have an autoimmune factor, perhaps an antibody directed against neuroblastoma that cross-reacts with the cerebellar cell antigen. Immune therapies such as steroids, intravenous immunoglobulin, and rituximab are being employed in the treatment of opsoclonus-myoclonus.

Table 225-1, Table 225-2, and Table 225-3 list the differential diagnosis of abdominal, pelvic, head, neck, and mediastinal tumors that may mimic neuroblastoma.

**Table 225-2** Differential Diagnosis of Head and Neck Tumors in Infants and Children

TUMOR <sup>a</sup>	AGE	CLINICAL SIGNS	LABORATORY FINDINGS
Non-Hodgkin lymphoma	>1 yr	Lymphadenopathy NR to antibiotics, immunodeficiency, EBV (in Africa)	Increased urate
Hodgkin disease	>10 yr	Lymphadenopathy NR to antibiotics; weight loss, night sweats, fever, pruritus	Increased ESR
Rhabdomyosarcoma	All	Orbital mass, hoarseness, persistent otitis, sinusitis	—
Neuroblastoma	Preschool	Heterochromia iridis, Horner syndrome, myoclonus-opsoclonus, raccoon eyes, skin nodules (infants)	Increased HVA, VMA, or both in urine; calcification
Retinoblastoma	Preschool	Cat's-eye reflex, strabismus, family history	Calcification

EBV, Epstein-Barr virus; ESR, erythrocyte sedimentation rate; HVA, homovanillic acid; NR, nonresponsive; VMA, vanillylmandelic acid.

<sup>a</sup>Other causes: infectious lymphadenopathy, histiocytosis, Caffey disease, acquired immune deficiency syndrome.

**Table 225-3** Differential Diagnosis of Mediastinal Tumors in Infants and Children

TUMOR <sup>a</sup>	AGE	CLINICAL SIGNS	LABORATORY FINDINGS
Non-Hodgkin lymphoma	All	Cough, respiratory distress, anterior mediastinal mass, immunodeficiency syndrome	Increased urate, malignant effusion
Hodgkin disease	>10 yr	Middle mediastinum lymphadenopathy NR to antibiotics, weight loss, night sweats, fever, pruritus	Increased ESR, increased copper
Neuroblastoma	Preschool	Posterior mediastinum, heterochromia iridis, opsoclonus-myoclonus, raccoon eyes, skin nodules (infants)	Increased HVA, increased VMA, calcification
Thymoma	>10 yr	Anterior mediastinum, myasthenia gravis, red cell aplasia, hypogammaglobulinemia	—
Germ cell or teratoma	All	Anterior mediastinum (rarely, posterior mediastinum), cough, wheeze, dyspnea	Increased AFP, increased hCG

AFP, Alfa-fetoprotein; ESR, erythrocyte sedimentation rate; hCG, human chorionic gonadotropin; HVA, homovanillic acid; NR, nonresponsive; VMA, vanillylmandelic acid.

<sup>a</sup>Other causes: infection, bronchogenic cysts, aneurysms, lipid tumors, thoracic meningocele.

### Evaluation

After the initial physical examination, evaluation of a child who has neuroblastoma requires radiologic examination of the area of primary disease, as well as of areas to which neuroblastoma metastasizes. A CT scan of the abdomen, pelvis, and chest should be performed. For children with cervical masses, the CT scan should include this area. Because paravertebral lesions may extend into the intervertebral foramina, any child who has such a lesion should be evaluated by MRI. A skeletal survey and a bone scan should be performed to detect bony lesions. Radiographs are useful for detecting small lytic lesions at the end of bones; the bone scan helps find lesions of the skull and tubular bones. Because of the frequency of metastatic involvement, bone marrow biopsy specimens should be obtained in all patients; the only exception may be patients with low-risk, resected tumors. Bilateral specimens should be obtained to increase the probability of detecting metastases. The liver should be examined by contrast CT scan in all patients and by biopsy in those who have abdominal disease. Metaiodobenzylguanidine (MIBG) is taken up by neuroblastomas and has

become a standard methodology used for staging and response assessment. Positron emission tomography (PET) scanning may also be helpful in assessing neuroblastoma.

The previously used Evans and St Jude staging systems were synthesized into the International Neuroblastoma Staging System. Stage 1 includes tumors with complete gross resection and microscopically negative ipsilateral and contralateral lymph nodes. Stage 2 tumors are unilateral tumors with complete or incomplete gross resections, but, at the most, only ipsilateral microscopically positive lymph nodes. Stage 3 includes tumors that cross the midline or unilateral tumors that have contralateral lymph node involvement. Stage 4 designates metastatic disease. Stage 4S (for special) tumors occur in infants younger than 1 year of age who have stage 1 or 2 primary tumors with dissemination limited to liver, skin, or bone marrow. More recently, limitations of this methodology of risk group assessment led to the development of the International Neuroblastoma Risk Group (INRG) Staging System, a system that stratifies on the basis of clinical factors identifiable before surgery.

Neuroblastoma is diagnosed by histologic examination after biopsy. In children who have localized disease, the biopsy specimen must be obtained from the primary tumor. For those who have metastatic disease, neuroblastoma cells can be identified in the primary tumor or in areas of metastases, including the bone, bone marrow, or liver. Neuroblastoma produces small round cells with scant cytoplasm that must be differentiated from other small round blue cell tumors of childhood, including lymphoma, leukemia, Ewing sarcoma, and retinoblastoma. Secretion of catecholamines from tumor granules results in increased levels of vanillylmandelic acid (VMA) and homovanillic acid (HVA) in 24-hour urine samples or in increased VMA/creatinine or HVA/creatinine ratios in spot urine samples. These findings can be used to confirm the diagnosis of neuroblastoma in children who have a small, round, blue cell infiltrate in the bone marrow. In addition, increased urinary catecholamine levels can be used to monitor the response to therapy. Ferritin and lactic dehydrogenase levels may be obtained and have prognostic significance in that increased levels predict a poor prognosis.

Amplification of the *N-myc* oncogene is an intrinsic biologic property of some neuroblastomas and has been associated with poor prognosis regardless of clinical stage (although it is most commonly seen in children who have advanced disease). Conversely, tumors that are hyperdiploid (DNA index >1) are sensitive to chemotherapy, resulting in a good prognosis. Specimens should be analyzed for both of these biologic features, which are used to determine risk groups for treatment purposes. Additional findings, such as the association of the tyrosine kinase receptor TrkA with good risk and the association of deletion of chromosomes 1p and 11q with poor risk, even in children with low- or intermediate-risk features, suggest that continued study of the molecular biology of neuroblastoma may lead to additional prognostic factors and new therapeutic approaches. Gene microarray technology may also contribute to identification of tumors with different biologic behavior.

### Management

Neuroblastoma is sensitive to both chemotherapy and radiotherapy. Surgical therapy alone may suffice for localized disease. In patients with lower risk disease, minimal residual disease may regress spontaneously. Although complete removal of the tumor offers the best chance of cure in higher-risk patients, often only a diagnostic biopsy is feasible. Tumor recurrence in such children is often at the site of the primary tumor. Surgical reduction after initial cytoreductive therapy may enhance the likelihood of cure.

Chemotherapy is the major modality of therapy in neuroblastoma. Complete and partial responses have been found with several agents, including cyclophosphamide, doxorubicin, cisplatin, epipodophyllotoxin, and vincristine. Ifosfamide, carboplatin, and topotecan are also effective agents. Combination therapy is used most intensively in the more advanced stages of disease.

A risk-stratified treatment approach is employed with neuroblastoma. In intermediate-risk neuroblastoma,

a high survival rate has been achieved with reduction of doses and number of chemotherapeutic cycles compared with the regimens used in earlier protocols.

In high-risk neuroblastoma, an aggressive multimodality treatment approach is necessary. Survival with conventional therapy remains inadequate for children older than 1 year of age who have stage 3 disease with unfavorable biologic features (eg, *N-myc* amplification) or stage 4 disease. However, recent studies have demonstrated that children between the ages of 12 and 18 months with metastatic disease, but nonamplified *N-myc*, have a more favorable prognosis and may not require the same intensity of therapy as children with amplified *N-myc*. These intensive regimens are at the limits of bone marrow tolerance. Myeloablative therapy followed by purged autologous stem cell transplantation to restore hematopoiesis improves event-free survival; the differentiating agent, *cis*-retinoic acid, improves survival for high-risk children, regardless of whether stem cell transplantation was used. Other retinoids, such as fenretinide, are actively being studied. The retinoids are of particular interest because their mechanisms include both differentiation and induction of apoptosis.

Neuroblastoma is a radiation-sensitive tumor. Although rarely needed in early-stage disease, radiotherapy may facilitate surgical resection of residual disease or may reduce the risk for recurrence in surgically unresectable disease. Emergent situations, such as a large mediastinal mass resulting in respiratory compromise or a dumbbell lesion protruding into the intervertebral foramen that causes cord compression, may be treated with radiation. Total-body irradiation is generally not a component of the preparative regimen used before hematopoietic stem cell transplantation, although radiation may be used for sites of residual disease in conjunction with stem cell transplantation. In the terminal stage of neuroblastoma, bone pain or compression of organs such as the trachea, bowel, or urinary tract may require palliative radiotherapy.

Investigations continue into other treatments to improve the outcome and potentially reduce the toxicities of therapy for children who have high-risk neuroblastoma. Overall success rates have improved for high-risk neuroblastoma by incorporation of autologous stem cell transplantation as consolidative therapy followed by 13-*cis*-retinoic acid to induce tumor cell maturation. The addition of chimeric anti-GD2 antibody ch14.18, combined with granulocyte-macrophage colony-stimulating factor and interleukin-2 has further improved the event-free survival for high-risk neuroblastoma patients in remission after stem cell transplantation. There are also promising data on the use of radiolabeled MIBG in high-risk neuroblastoma patients. This therapeutic modality is being investigated in cooperative group trials. Other novel approaches include inhibition of TrkB activity with Lestaurinib and *ALK* inhibition.

### Prognosis

Age of the child and stage of disease seem to be the most important predictors of survival. Children who are younger than 1 year of age do much better than those who are older than 2 years of age. Children who have stage 1, 2, or 4S neuroblastoma with favorable

biologic features have survival rates higher than 90%. Biologic factors of the tumors, including *N-myc* amplification, also adversely affect outcome. Although some studies dispute the poor prognosis of *N-myc*-amplified tumors in infants, other studies report a significantly lower survival rate for these children. Long-term survival for children who have stage 3 neuroblastoma has improved, with children younger than 1 year of age and with those who have favorable biology having, respectively, survival rates of 100% and 90% at 4 years. Thus, intensive multiagent chemotherapy seems to result in improved cure rates for these children. In studies of children with stage 4 disease who are treated with stem cell transplantation, event-free survival is 23% to 47% at 3 to 6 years after treatment. Skeletal disease and persisting bone marrow involvement were predictive of a poorer outcome, and children who have a complete response to chemotherapy benefit most from transplantation.

### Follow-up

Although late recurrences have been reported, most tumors recur while children are receiving therapy or shortly afterward. Close follow-up with physical examination and radiologic studies should continue after completing therapy. Urinary catecholamine levels may be useful in the surveillance of children who had increased values at diagnosis. Children should be monitored for late toxicities of chemotherapy (eg, cyclophosphamide, doxorubicin, cisplatin) and radiotherapy. High-dose therapy associated with autologous hematopoietic stem cell procedures may result in significant late effects, including hearing loss, renal insufficiency, growth impairment, and gonadal failure.

## RETINOBLASTOMA

Retinoblastoma is the most common intraocular cancer in childhood. Retinoblastoma is diagnosed 95% of the time before age 5 years. In the United States, the mean age-adjusted incidence rate of retinoblastoma is 11.8 cases per million children younger than 4 years. The incidence of retinoblastoma does not vary by race or gender.

Two-thirds of these cases occur before age 2 years. Older age is usually associated with more advanced disease and a poorer prognosis. No difference by gender, race, or left versus right eye has been found. Bilateral disease represents a hereditary form of this tumor that occurs at an earlier age and is present in 30% to 40% of patients. Unilateral disease is a sporadic form of the tumor in 90% of children with this presentation; the other 10% have familial retinoblastoma.

This tumor is the model for understanding the role of genetics in the development of malignancy. The pediatrician plays an important role in initially detecting this disorder and in providing support to the family, who may carry a genetic predisposition to this malignancy.

### Etiology

Two independent mutations must occur in a single retinal cell for retinoblastoma to develop. The initial mutation may occur in a germinal cell (inheritable form) or in the somatic retinal cell itself (sporadic

form). Children who have an abnormality in the germinal cell have 1 mutation in each retinal cell. A second mutation is relatively likely to occur, causing retinoblastoma (often multiple, bilateral tumors). If the initial mutation arises in a retinal cell, then it must be followed by a second mutation in the same cell for the sporadic form of retinoblastoma to arise. The likelihood of 2 such events is low; hence, single unilateral tumors develop. Because the germinal cell is not involved, the mutation is not inherited.

A child who has a family history of retinoblastoma or bilateral retinoblastoma has a germinal mutation and, therefore, the hereditary form of the disease. Penetrance is approximately 90%; thus, these patients have a 45% chance of transmitting retinoblastoma to their children. The germinal mutation also may have arisen in an unaffected parent or in a parent who had an undiagnosed retinal lesion. Parents ought to undergo an ophthalmologic examination. If the first child of noncarrier parents has unilateral retinoblastoma, then their second child has a 1% risk for being affected; siblings should have ophthalmologic examinations also. All families should be referred for genetic counseling.

In some families, recombinant DNA techniques may aid in determining whether the disease is hereditary and which relatives are predisposed to retinoblastoma. Abnormalities of chromosome 13q14 have been detected in patients who have retinoblastoma. This retinoblastoma (*Rb*) gene has been cloned, and the *Rb* gene product is a regulator at the cell cycle checkpoint between G1 and entry into S phase. Deletion or dysfunction of the gene also has been found in nonretinal tumors such as osteosarcomas, soft-tissue sarcomas, and breast carcinomas. Testing patients and family members for mutations in the *Rb* gene requires sophisticated techniques and fails to detect the abnormality in approximately 20% of children with bilateral disease. Improving the ease, availability, and sensitivity of testing for families with retinoblastoma is a goal for the future. Other chromosomal abnormalities have also been identified in retinoblastoma, and as with other pediatric malignancies, they are being studied for their relationship to tumorigenesis and biologic behavior. Another area of research is the role of human papillomavirus in sporadic retinoblastoma.

### Clinical Manifestations

Infants who have a family history of retinoblastoma should be screened by examination under anesthesia at birth and every 2 to 4 weeks initially, then again at increasing intervals to detect disease before the occurrence of clinical symptoms. Screening should continue until age 5 years for these patients and for patients diagnosed with unilateral disease. Pediatricians and parents usually detect the abnormality in children who have the sporadic form of disease by routine evaluation because young children rarely complain of unilaterally decreased vision. The pediatrician plays an important role in detecting the signs and symptoms of retinoblastoma. Leukocoria, or cat's eye reflex, describes a whiteness detected in the pupillary area caused by a large retrolental mass. It is the most commonly encountered sign of retinoblastoma. If a

normal red reflex is not present in a young child, then it should be investigated. The second most common presenting feature is strabismus. Although common in childhood because of abnormalities of ocular muscle strength, strabismus rarely arises suddenly in a child who has had normal extraocular movements. In rare cases, pain in the eye may occur as a result of glaucoma. New-onset strabismus or an abnormal red reflex (leukocoria) requires prompt ophthalmologic evaluation.

The differential diagnosis of retinoblastoma includes Coats disease, retrolental fibroplasia, persistent hyperplastic primary vitreous, toxoplasmosis, *Toxocara canis* infection, and other causes of severe uveitis. Although children sometimes have non-neoplastic disorders at the time of enucleation, this occurrence is uncommon with newer diagnostic methods, including ultrasonography and MRI. If retinoblastoma is a possibility, then referral should be made to an ophthalmologist experienced in ophthalmologic oncology who has a working relationship with radiation and pediatric oncologists.

### Evaluation

Examination under anesthesia after dilating the pupils is necessary to fully evaluate the retina in a young child. Ultrasonography is useful to evaluate the mass, particularly if the fundal examination is obscured by hemorrhage or retinal detachment. Calcification in retinoblastoma may be apparent on radiograph, ultrasound examination, or CT scan. The CT scan helps demonstrate the extent of intraocular disease and may detect possible extraocular extension. Magnetic resonance imaging can help to evaluate the tumor involvement with the optic nerve, the subarachnoid, and the brain. Biopsy is not a feasible method of diagnosis for retinoblastoma. If a family history of bilateral disease exists, then a tissue diagnosis is unnecessary. In many cases of unilateral disease, enucleation may be necessary to establish the diagnosis and to treat the tumor. For high-risk children, bone marrow and cerebrospinal fluid specimens are obtained for evidence of dissemination. The extent of local disease (extension beyond the globe or optic nerve infiltration) is assessed at the time of enucleation. The Reese-Ellsworth classification has been used for decades as a method to describe tumors based on size, location, and multiplicity. Its original intent was to predict prognosis and vision in eyes treated with different radiation techniques, but its consistent use maintained its usefulness as therapy evolved. However, new classifications have been proposed to account for the emergence of new therapies, particularly chemotherapy. The International Classification for Intraocular Retinoblastoma, a new classification system for retinoblastoma, was incorporated into the most recent COG treatment studies. It has assisted with risk stratification and also guidance in determination of which patients can be spared enucleation or external-beam radiotherapy (EBR) and still attain cure.

### Management

Treatment of retinoblastoma is individualized based on the extent of disease and the possibility for vision preservation. Treatments available include enucleation,

EBR, plaque brachytherapy, cryotherapy, photocoagulation, and chemotherapy. Most children who have unilateral sporadic disease have large lesions and compromised vision. Enucleation is usually required, with removal of the longest segment of the optic nerve possible. Photocoagulation and cryotherapy are used for small lesions, most commonly in children who have hereditary bilateral disease. Until recently, radiotherapy was the standard of care for children who had massive bilateral disease; but now, chemotherapy is used to allow local therapy to preserve vision. Significant tumor shrinkage can be achieved, but local therapy is required for cure. Some evidence suggests that chemotherapy also prevents pineoblastoma, a usually fatal second cancer in children with hereditary retinoblastoma. The most commonly used agents are vincristine, carboplatin, and etoposide. Radiotherapy, enucleation, or a combination of both can be avoided with the use of chemotherapy in intermediate-stage disease; chemotherapy also plays an increasing role in the treatment of advanced-stage disease. Periocular administration of carboplatin chemotherapy has also been studied and used in specific clinical situations. Emerging therapy also includes the use of transpupillary thermotherapy with or without adjuvant chemotherapy.

Cyclosporine has been used with chemotherapy to overcome multidrug resistance and has been shown to improve the long-term response to chemotherapy, although definite benefit remains to be proved. Bone marrow transplantation or peripheral blood stem cell support after high-dose therapy for the treatment of recurrent disease has been reported.

### Prognosis

Survival of children who have retinoblastoma is excellent; more than 85% have no recurrence of their tumor, and survival from the primary tumor is more than 95%. Unfortunately, children who have hereditary retinoblastoma have a high incidence of a second malignancy. Approximately 50% of second malignancies occur within the radiation field; osteosarcoma or other sarcomas in particular are common. Children irradiated when they are younger than 1 year of age are at increased risk. Approximately one-third of such children have a second malignancy within 15 years. By 30 years, up to two-thirds have a second malignancy. Avoiding radiotherapy may reduce, but not eliminate, this risk.

### Follow-up

Children who were treated for retinoblastoma will need close follow-up for evidence of recurrence and for second malignancies. Most recurrences happen within 3 years of diagnosis. Examinations under anesthesia should be performed every 2 to 3 months during the first year, every 3 to 4 months during the second year, and every 6 months thereafter until age 6 years. Long-term risk depends on treatment. After enucleation, a prosthesis is necessary. Radiation impairs orbital growth and increases the risk for cataract development and retinal vascular injury. Growth and pubertal development are usually unaffected by orbital radiation, but monitoring hypothalamic-pituitary axis function is warranted. The risk for a second malignancy

is high in children who have bilateral or familial disease, particularly in the radiation field. Medical care should be sought promptly for unexplained masses, pain, or other symptoms.

## RHABDOMYOSARCOMA

Rhabdomyosarcoma is one of the small, round, blue cell tumors of childhood (along with neuroblastoma, Ewing sarcoma, and lymphoma). It arises from embryonal mesenchyme that can differentiate into skeletal muscle. Rhabdomyosarcoma occurs almost anywhere in the body, even in sites that do not normally contain skeletal muscle. It can be an aggressive tumor that disseminates early in the course of disease. Before the advent of chemotherapy, cure required extirpative surgery of localized disease and then radiotherapy. Marked improvement in prognosis, with survival rates increasing from less than 20% in the 1960s to more than 70% in the late 1990s, is the result of the multidisciplinary cooperative group approach of the Intergroup Rhabdomyosarcoma Study.

Rhabdomyosarcoma is the most common pediatric soft-tissue sarcoma, accounting for 2% to 4% of childhood malignancies and 5% to 15% of childhood solid tumors. Its annual incidence among children through 18 years of age in the United States is 4.5 per million; thus, about 400 new cases are diagnosed each year. The incidence in boys is greater than in girls, and it is more common in white children than in black children. Fifty percent of cases are seen in the first decade of life. The incidence of alveolar rhabdomyosarcoma does not vary based on age or gender. However, there is a bimodal distribution for embryonal rhabdomyosarcoma with a smaller second peak in adolescence for males only.

### Etiology

The cause of this tumor is unknown. It has occurred in association with neurofibromatosis, with Beckwith-Wiedemann syndrome, in families who have a history of multiple tumors, and in children who have congenital abnormalities of the CNS, the heart, the gastrointestinal tract, and the urinary tract. Germline mutations in the *p53* tumor suppressor gene, which cause Li-Fraumeni syndrome, are associated with childhood sarcomas, particularly rhabdomyosarcoma. Families of children with sarcomas at a young age should consider genetic testing for *p53* mutations and genetic counseling. Families diagnosed with Li-Fraumeni syndrome can proceed with routine cancer screenings to aid in earlier diagnosis of malignancy.

Two major histopathologic subtypes of rhabdomyosarcoma have been noted—embryonal and alveolar. Embryonal rhabdomyosarcoma, which accounts for more than one-half of cases, may have LOH at 11p15; the alveolar subtype is associated with characteristic chromosomal translocations involving the *PAX* gene, most commonly t(2;13). Alveolar rhabdomyosarcoma is more common in extremity and trunk sites and in older children. Younger children who have alveolar rhabdomyosarcoma may have t(1;13), which is associated with a somewhat better prognosis than t(2;13), particularly in children with metastatic disease. Molecular testing can be used in addition to histopathologic

analysis to ensure accurate diagnosis. As in other pediatric malignancies, further investigation of the cytogenetic alterations identified in the histopathologic subtypes will provide insight into tumorigenesis. There is ongoing analysis about the molecular classification and clinical characteristics of the histopathologic subtypes of rhabdomyosarcoma. Undifferentiated sarcomas do not express lineage markers, but have traditionally been treated by the same regimens used to treat rhabdomyosarcoma.

### Clinical Manifestations

Rhabdomyosarcoma typically produces a painless mass with poorly defined margins. A mass may not be palpable, but patients may experience disturbance of a normal body function resulting from the presence of tumor. Pain may also be a presenting symptom. About 40% of rhabdomyosarcomas arise in the head and neck region, 25% in the genitourinary region, 20% in the extremities, and the remainder in the trunk and other sites. One common site of involvement is the orbit, in which swelling, proptosis, discoloration, and limitation of extraocular motion occur. Children who have a tumor of the head and neck may have hoarseness, difficulty swallowing, nasopharyngeal polyps, nasopharyngeal obstruction, decreased hearing acuity, persistent otitis, sinusitis, bloody nasal discharge, parotitis, or cranial nerve palsies. In parameningeal sites, penetration to the brain may cause headache, vomiting, or diplopia. A retroperitoneal tumor may exhibit as a mass or partial or complete bowel obstruction. Vaginal bleeding, pelvic or perineal masses, hematuria, urinary frequency, and urinary retention suggest genitourinary tract involvement. A tumor may even be extruded from the bladder or female genital tract. A hydrocele, incarcerated hernia, testicular torsion, or testicular mass may be an indication of paratesticular rhabdomyosarcoma. Symptoms may be related to metastatic disease, such as pain or refusal to ambulate resulting from bone metastases. Patients may also have systemic symptoms, such as fever, fatigue, or weight loss.

### Evaluation

Initial evaluation should include a complete history and physical examination. Radiographs, CT scans, or MRI, and, in some instances (eg, genitourinary tract), ultrasound examination of the involved and adjacent areas should be performed. For genitourinary disease, a cystourethrogram, barium enema, and cystoscopic and pelvic examinations may also be needed. There is an emerging role for PET with fluorine-18-fluorodeoxyglucose (FDG) scans in the evaluation of rhabdomyosarcoma. Positron emission tomography scans can identify areas of possible metastatic disease not seen by other imaging modalities and may be predictive of outcome. Future studies will determine whether PET will become a standard imaging tool at diagnosis in rhabdomyosarcoma.

Bone surveys, bone scan, bilateral bone marrow aspirate and biopsy, and chest and abdomen CT scan are necessary to assess for metastatic disease. Basal skull erosion may be seen by CT scan, and spinal fluid may reveal meningeal disease in children who have parameningeal tumors. If spinal cord symptoms are

present, then a spinal MRI is necessary. Biopsy of the lesion establishes the diagnosis and should be performed before extensive resection. Rhabdomyosarcomas are assigned a stage determined by preoperative extent and site of disease and to a clinical group based on postoperative residual disease.

### Management

Rhabdomyosarcoma is a tumor that requires a multi-therapeutic approach, including chemotherapy, surgery, and radiation. Aggressive surgical approaches have become less essential as chemotherapy and radiotherapy have become more efficacious.

The initial surgical procedure should be a diagnostic biopsy. A wide resection of the primary tumor, including surrounding normal tissue, is preferable if excessive functional and cosmetic morbidity can be prevented. Complete resection is correlated with a better outcome, but is possible in only approximately 20% of patients. Extensive en bloc lymph node dissection is no longer indicated; however, biopsy should be performed on large regional nodes. Second-look surgery after chemotherapy may allow resection with reduction of surgical morbidity, provides assessment of therapeutic response, and potentially reduces the dose of radiotherapy.

All patients with rhabdomyosarcoma require multi-agent chemotherapy. Regimens are determined by risk group, which is based on stage, group, histology, and age. Vincristine, actinomycin D, and cyclophosphamide are the primary agents. Although other chemotherapy agents have been studied and have activity, none has proved better than this combination. The addition of topotecan in intermediate-risk rhabdomyosarcoma did not improve event-free survival. Other new agents continue to be developed and studied to improve the treatment of high-risk and relapsed patients. Vincristine with irinotecan is promising, with a response rate of 70% in children with recurrent or refractory disease.

Rhabdomyosarcoma is an infiltrative disease, and radiation portals should include the entire extent of tumor volume. Radiation is required for children with embryonal histology who have residual disease after surgery and for all children with alveolar histologic features. High doses of radiation (50 to 65 Gy) can control local residual disease very well, but substantial late morbidity results. Lower doses of radiation may be indicated with good tumor response or complete surgical resection.

### Prognosis

The likelihood of survival for patients who have rhabdomyosarcoma is determined by the site and the stage of disease. Overall, survival is 73% at 5 years from diagnosis. The prognosis is particularly good for patients who have orbital tumors, nonbladder and nonprostate genitourinary tract tumors, and localized tumors that can be resected fully (90% to 95% long-term survivors). Children with stage IV (metastatic) disease who are younger than 10 years of age and have embryonal histology have a better prognosis than older children who have stage IV disease. Extremity lesions are particularly difficult to treat, perhaps because many co-occur with metastatic disease.

Treatment of genitourinary primary tumors has improved markedly in recent years with the use of extensive chemotherapy. Pelvic exenteration and other morbid surgeries can now be avoided in most patients, and radiotherapy may be avoided in some. Cranial radiation and intrathecal chemotherapy were once used in all children who had parameningeal lesions. Intrathecal chemotherapy is rarely used, and early radiotherapy is reserved for children who have basal skull lesions, CNS involvement, or spinal cord compression.

Twenty percent of children have metastatic disease at diagnosis; these children continue to have a low likelihood of survival. Current studies indicate that 25% to 30% of these children will survive 5 years from diagnosis. Meta-analysis has not shown that hematopoietic stem cell transplantation improves outcome; however, new agents may offer hope to these patients. Eighty percent of recurrences occur within 2 years of treatment. Local relapse is most common, although distant spread to the lungs, CNS, lymph nodes, bone, liver, bone marrow, and soft tissues does occur. For children who experience relapse, survival depends on histologic features, initial grouping, and staging. Shorter time to recurrence was associated with higher risk for mortality from recurrent rhabdomyosarcoma. Twenty percent of children who experience relapse have favorable features with 50% 5-year survival; the other 80% have only 10% 5-year survival.

### Follow-up

Children who have rhabdomyosarcoma should receive close follow-up for evidence of recurrent disease for at least 3 to 5 years from the time of diagnosis. Computed tomography or MRI of the primary site, chest CT scans, and bone scans are frequently used for surveillance. Radiotherapy often results in unacceptable cosmetic effects in patients who have orbital tumors. For children who have orbital or other tumors located in a region of the head or face and received radiation to the sinuses, hypothalamus, and pituitary gland, sinusitis is a common complaint, and hormone levels (eg, growth hormone, gonadotropins) may need monitoring. Patients should also be monitored for any potential late effects of chemotherapeutic agents (Table 225-4).

## GERM CELL TUMORS AND TERATOMAS

Germ cell tumors are growths arising from primordial germ cells. They account for 3% of tumors in children, with an annual incidence of approximately 4 cases per million children younger than 15 years of age. Incidence is greatest in adolescents and very young children. The sacrococcygeal teratoma (named from the Greek *teras*, meaning *monster*) is the most common germ cell tumor of childhood and is benign in 80% of children. It occurs in 1 per 35,000 live births and is more common in girls than in boys (2:1 to 4:1). Sixty percent of childhood germ cell tumors originate in other sites, including the gonads, mediastinum, intracranial region, and retroperitoneum.

### Etiology

Germ cells appear in the yolk sac endoderm, migrate around the hind gut to the genital ridge on the posterior

**Table 225-4 Long-Term Side Effects of Chemotherapy<sup>a</sup>**

DRUG	POTENTIAL ORGAN DAMAGE	EVALUATION
Anthracyclines (eg, doxorubicin)	<i>Cardiac:</i> myocardial damage, congestive failure, arrhythmias	<i>History:</i> exercise intolerance, palpitations; ECG (QTc interval); echocardiogram scheduled based on age, dose, and radiation exposure; Holter monitor; exercise ECG; exercise nuclear angiography
Bleomycin	<i>Pulmonary:</i> fibrosis, impaired diffusion capacity, exacerbated by increased oxygen delivery (eg, during anesthesia or scuba diving)	<i>History:</i> shortness of breath, dyspnea on exertion, cough; chest radiograph and pulmonary function tests (with diffusion capacity) baseline and with symptoms
Cyclophosphamide, ifosfamide	<i>Gonadal:</i> infertility, sterility, early menopause	<i>History:</i> menses, question of fertility; luteinizing hormone, follicle-stimulating hormone, testosterone or estradiol during pubertal development, or if a problem with fertility or amenorrhea (or both) exists; semen analysis (as required to conceive)
	<i>Bladder:</i> hemorrhagic cystitis	Urinalysis annually
	<i>Marrow:</i> secondary acute myeloblastic leukemia	Complete blood cell count annually
Lomustine (CCNU) Carmustine (BCNU) Cisplatin	Pulmonary, gonadal	Pulmonary, gonadal evaluation
	<i>Kidney:</i> decreased glomerular filtration rate	Serum creatinine baseline and per guidelines
	<i>Ears:</i> hearing loss (high frequency)	Creatinine clearance baseline and per guidelines
		Audiogram baseline and per guidelines
Methotrexate	Liver dysfunction <i>CNS:</i> learning impairment (high intravenous dose)	Liver function tests baseline and per guidelines Neuropsychology testing baseline and per guidelines
6-Mercaptopurine, 6-thioguanine, actinomycin D	Liver dysfunction	Liver function tests baseline and per guidelines

CNS, Central nervous system; ECG, electrocardiogram.

<sup>a</sup>See [www.survivorguidelines.org](http://www.survivorguidelines.org) for more details.

abdominal wall of the embryo, and congregate, becoming part of the developing gonad. A slightly aberrant path of migration may account for the occurrence of extragonadal germ cell tumors along the dorsal wall of the embryo in midline sites (sacroccygeal, retroperitoneal, mediastinal, and pineal regions). Children who have sacroccygeal teratomas have an approximately 15% incidence of associated anomalies (eg, imperforate anus, rectal stenosis). An association with a family history of twinning resulted in early theories suggesting that teratomas were abortive attempts at the development of twins. Of interest, the common sites of teratomas—brain, mediastinum, abdomen, and sacroccygeal region—are all sites of twin attachment. A genetic tendency for abnormal germ cell development may exist in some families. These tumors have been reported to develop in siblings, twins, and subsequent generations. Gonadal dysgenesis has been associated with dysgerminoma or gonadoblastoma. The type of germ cell tumor that forms is determined by the subsequent development of the germ cell; those that maintain their total potentiality become embryonal sarcomas. The development of extraembryonic structures results in the formation of choriocarcinomas (placental tumors) or endodermal sinus tumors (yolk sac tumors). Mixed

tumors are not uncommon. Seminomas or dysgerminomas arise when the gonads differentiate. Teratomas form as a result of embryonal differentiation into ectoderm, mesoderm, and endoderm.

### Clinical Manifestations

The clinical manifestations of a germ cell tumor depend on the tumor's location. Sacroccygeal tumors occur as a mass between the anus and the coccyx. An abnormality of the overlying skin may be noted. An intrapelvic tumor may be associated with an external tumor or may be the only evidence of disease, noted by the onset of urinary or rectal obstruction. The incidence of intradural tumor extension is 3% to 5%. Maternal polyhydramnios may be associated with infantile sacroccygeal teratomas.

Ovarian tumors in infants occur as abdominal masses. Older girls have symptoms of abdominal pain, nausea, vomiting, constipation, or urinary tract obstruction, with palpable masses noted in 50%. Torsion or hemorrhage within the tumor may be responsible for acute abdominal pain; 5% of such children have bilateral tumors. Vaginal germ cell tumors in preschool-aged girls (<3 years) may cause bloody vaginal discharge.

Testicular tumors most often occur as symptom-free scrotal masses, sometimes with a coexisting hydrocele. Torsion of the tumor in an undescended testis may result in acute abdominal pain. An undescended testis is an established risk factor for testicular germ cell tumor. Because the ipsilateral or contralateral testis may be affected, an intrinsic testicular defect is likely.

Retroperitoneal teratomas that occur in children younger than 2 years are usually symptom-free abdominal masses. In older children, anorexia, vomiting, or abdominal pain may be noted. Intradural extensions may also occur, and gastric and hepatic tumors have been reported. The symptoms of children who have germ cell tumors of the anterior mediastinum include coughing, wheezing, dyspnea, and chest pain. Newborns may require immediate intubation for respiratory distress caused by mediastinal, cervical, or oropharyngeal germ cell tumors. Intrapericardial tumors can cause heart failure and cardiac tamponade. In the fetus with an oropharyngeal mass, the inability to swallow can cause maternal polyhydramnios. Cranial tumors (80% in the pineal region) cause hydrocephalus and increased intracranial pressure in infants. Teenagers have headaches, lethargy, vomiting, diabetes insipidus, seizures, and visual disturbance, especially loss of upward gaze.

The differential diagnosis of children who have germ cell tumors depends on the location of the primary tumor. For children who have sacrococcygeal masses, meningocele is the most frequent alternative diagnosis. Abdominal or pelvic masses may be the result of neuroblastoma, Wilms tumor, rhabdomyosarcoma, or lymphomas. Nonmalignant disorders such as hydronephrosis, benign ovarian cysts, constipation, and splenomegaly must be considered. Anterior mediastinal tumors include T-cell lymphoma, leukemia, or thymoma. The differential diagnosis for an intrascrotal mass includes testicular torsion, epididymitis, and testicular infarction. (See Table 225-1 and Table 225-3 for details of the differential diagnosis of germ cell tumors.)

### Evaluation

As in any ill child, evaluation includes a thorough physical examination. For children who have a sacrococcygeal mass or abdominal pain, particular attention should be paid to the abdominal and rectal examination. A pelvic examination (performed under anesthesia in young girls) will be necessary if an ovarian or a vaginal tumor is suspected.

Thorough evaluation by CT, ultrasound, or both is essential. A CT scan of benign germ cell tumors will often reveal calcifications. A teratoma frequently shows cystic and solid components, including fat, on radiologic examination. Malignant germ cell tumors often have areas of hemorrhage and necrosis. A chest CT scan and bone scan should be performed to detect pulmonary and bony metastases.

Malignant germ cell tumors that have evidence of extraembryonic differentiation often produce proteins elaborated by the corresponding normal embryonic structure. Serum levels of these markers, alpha-fetoprotein (AFP) and  $\beta$ -human chorionic gonadotropin ( $\beta$ -hCG), should be assayed before surgery. Alpha

fetoprotein is found in germ cell tumors that have endodermal sinus tumor histologic features. The evaluation of AFP levels must account for their increase during fetal development; they do not return to normal levels until the child is about 9 months of age.  $\beta$ -hCG, a glycoprotein normally produced by specialized placental cells, is present in increased quantity in children who have choriocarcinomas, children who have hydatidiform moles, and women during pregnancy. In adolescent girls who have an abdominal mass and increased  $\beta$ -hCG, pregnancy should not be assumed, especially if she denies sexual activity or symptoms are atypical. Detection of AFP or  $\beta$ -hCG improves the ability to monitor the disease status. The rate of disappearance after resection reflects the adequacy of the tumor removal. With response to chemotherapy, the levels of these proteins decrease. A significant increase in these levels suggests disease recurrence.

### Management

Germ cell tumors may have components of teratoma, endodermal sinus tumor, embryonal carcinoma, choriocarcinoma, seminoma, or dysgerminoma. Teratomas are classified as mature or immature or as teratoma with malignant components. Mature teratomas (well-differentiated tissues) and immature teratomas (embryonic-appearing neuroglial elements and mature elements) are most commonly found in infants, although more than one-half of germ cell tumors that have a major component of immature teratoma are mixed tumors, all of which will contain elements of yolk sac tumor. Malignant evolution may occur years after removal of an apparently benign tumor, particularly in the sacrococcygeal area. For this reason, complete excision of the coccyx is often suggested, and close follow-up is necessary.

In the past, malignant teratomas, embryonal carcinomas, endodermal sinus tumors, and choriocarcinomas were almost always fatal. Complete surgical resection was rarely attained and only infrequently curative. Only embryonal carcinoma of the infant testis might be cured by radical orchiectomy. In the 1960s, however, the efficacy of methotrexate chemotherapy for gestational choriocarcinomas and testicular germ cell tumors was demonstrated. Ovarian tumors responded to vincristine, actinomycin D, and cyclophosphamide. In the 1970s, additional agents such as vinblastine and cisplatin were found to have significant single-agent response in testicular germ cell tumors of young men. The combination of these 2 agents with bleomycin produced a 70% complete remission rate and a 55% long-term disease-free survival rate for patients who have advanced testicular carcinoma. The regimens initially studied in adults also proved effective in children. Chemotherapy is now the standard for significant subsets of children with germ cell tumors.

Current studies stratify patients as follows: low risk—stage I testicular and ovarian tumors; intermediate risk—stages II to IV testicular, stages II and III ovarian, stages I and II extragonadal malignant germ cell tumors; and high risk—stages III and IV extragonadal tumors. Therapies include surgery and observation for

low-risk children, and standard therapy with cisplatin, etoposide, and bleomycin (PEB) for intermediate-risk children. The advent of cisplatin-based chemotherapy has significantly improved the survival rates for pediatric extracranial germ cell tumors, with 5-year survival rates of more than 90%. The Children's Cancer Group and the Pediatric Oncology Group studied the use of PEB for germ cell tumors. Specifically, they conducted randomized trials to explore the use of high-dose cisplatin in children with extragonadal and high-risk germ cell tumors. The intensification of cisplatin provided an improvement in event-free survival, but not in overall survival. Additionally, the use of high-dose cisplatin had a higher incidence of ototoxicity and nephrotoxicity.

### Prognosis

The French Society of Pediatric Oncology identified 3 prognostic groups for children older than 1 year of age who had localized disease. Children with stage III disease (more than microscopic residual disease), sacrococcygeal or mediastinal primaries, and AFP more than 10,000 ng/mL had a 43% 3-year disease-free survival. Stage I disease (complete resection) or stage II disease (microscopic residual), testicular, ovarian, perineal, or retroperitoneal primary tumor, and AFP less than 10,000 ng/mL were associated with a 100% 3-year disease-free survival. The remaining children were in an intermediate-prognosis group and had an 81% disease-free survival rate. This study also detected improved prognosis for children treated with cisplatin versus carboplatin. The prognosis continues to improve, with event-free survival rates for most patient groups better than 80% and up to 100%, with overall survival rates of 90% to 100%.

The prognosis for a teratoma depends on its degree of maturity and age. Sacrococcygeal teratomas are usually benign in children younger than 2 months; thereafter, the likelihood of malignant evolution increases rapidly. This factor may be the reason that intrapelvic teratomas that are not detected early often are found to be malignant. Mediastinal teratomas behave benignly in children and young teenagers; in older patients, they are more aggressive. Cervical and intracranial teratomas in infants are usually benign; those in adolescents and adults are often malignant.

Immature teratomas can be treated with surgery alone, with event-free survival rates of 97.8%, 100%, and 80% for children who have ovarian, testicular, and extragonadal tumors, respectively. For children who experience relapse, cisplatin-based chemotherapy offers an excellent chance of cure.

### Follow-up

The response of malignant germ cell tumors to chemotherapy is encouraging, but relapse may occur as many as 10 years from the time of diagnosis. Late-brain metastases have also been described. For this reason, close follow-up care is essential, including frequent physical examinations, radiologic evaluations, and monitoring AFP and  $\beta$ -hCG levels, if they are found to be high at diagnosis. Salvage therapy may prolong survival or even provide a cure. Late effects of the chemotherapeutic agent administered

(eg, bleomycin, cisplatin) should be monitored (see Table 225-4).

## EWING FAMILY OF TUMORS

The Ewing family of tumors includes Ewing sarcoma of bone, extraosseous Ewing, and peripheral primitive neuroectodermal tumors (PNETs). These tumors are malignant tumors that usually arise in bone, but may also occur in soft tissues. A PNET of the chest wall is referred to as *Askin tumor*.

The Ewing family of tumors accounts for 3% of childhood cancers and is the most common bone tumor in children younger than 10 years. In the second decade of life, it is second in incidence to osteosarcoma. The peak incidence is between the ages of 11 and 17 years, when the annual incidence is approximately 7 per million. Ewing sarcoma is extremely rare in children younger than 5 years of age or older than 30 years of age, as well as in black and Asian children.

### Etiology

The Ewing tumor is a primitive small, round, blue cell tumor. These tumors are of neural origin, with variable degrees of differentiation. Most share a common chromosomal translocation, t(11;22). The resulting gene fusion rearrangements provide insight into tumorigenesis of these malignancies; specific fusion products may have prognostic significance. No evidence suggests hereditary transmission of Ewing sarcoma, nor has it been associated with known congenital syndromes or constitutional karyotypic abnormalities. No specific environmental risk factors have been identified.

### Clinical Manifestations

Children who have Ewing sarcoma most commonly consult the physician for pain. Swelling may also be present. Symptoms often begin insidiously, several months before diagnosis, and may initially be attributed to trauma. At the time of diagnosis, a mass is palpable in 60% of patients resulting from the propensity of this tumor to break through the bony cortex and involve the surrounding tissue. This disruption of the cortex may also result in a pathologic fracture. The primary tumor site is evenly distributed between central and extremity lesions. The primary lesion is most often found in the femur (22%), the fibula or tibia (21%), or the pelvis (22%). The ribs and vertebrae are other common sites of origin. Demonstrable metastatic lesions are present in 14% to 35% of children, occurring in the lungs, bones, lymph nodes, and bone marrow. Central nervous system involvement is uncommon.

The differential diagnosis includes osteosarcoma, osteomyelitis, benign bone tumors, and bone cysts. Other tumors that occasionally involve the bone and have a similar histologic pattern of small round cells include lymphoma, leukemia, neuroblastoma, and rhabdomyosarcoma (Table 225-5).

### Evaluation

A radiograph should be obtained in a patient who has a mass overlying bone or bone pain that is not characteristic of trauma (by lack of history or prolonged duration of symptoms). Radiographs of a bone that

**Table 225-5** Differential Diagnosis of Malignant Tumors Involving the Extremities

TUMOR <sup>a</sup>	AGE	CLINICAL SIGNS	IMAGING AND LABORATORY FINDINGS
Ewing sarcoma	≥5 yr	Pain, swelling; genitourinary or skeletal anomaly; weight loss, fever; malaise (metabolic)	Onion skin appearance on radiograph; elevated LDH
Osteogenic sarcoma	Teens	Pain, swelling; familial retinoblastoma; prior radiation to bone; Paget disease	Codman triangle (cortical elevation, new bone formation); sunburst ossification of soft tissue; soft tissue mass; increased alkaline phosphatase level
Lymphoma	All	Pain, swelling	Elevated LDH or uric acid associated with rapidly growing lymphomas
Fibrosarcoma	Infants, teens	Painless mass; prior radiation; plastic implant	—
Rhabdomyosarcoma	All	Mass	—
Synovial sarcoma	Teens	Mass	Calcification (40%)

LDH, lactate dehydrogenase.

<sup>a</sup>Other causes: trauma, bone cysts, osteomyelitis.

has Ewing sarcoma often show a destructive lesion in the diaphysis. An onion-skin appearance arises from periosteal elevation and subperiosteal new bone formation associated with tumor extension through the cortex. A mottled pattern may be seen as a result of bone destruction, sclerosis, and cystic formation. An associated soft-tissue mass occurs in more than 50% of children who have primary tumors of long bones. Computed tomography and MRI are necessary to determine the extent of the primary lesion.

Radionuclide bone scanning detects primary and metastatic lesions, but it is not particularly useful in determining the extent of the primary disease. A CT scan of the chest is necessary to determine whether pulmonary lesions are present. The possibility of bone marrow involvement should be evaluated by bilateral bone marrow aspirates and biopsies. Identification of micrometastases in the bone marrow by polymerase chain reaction may identify high-risk patients without other evidence of metastases. Cerebrospinal fluid should be examined in patients who have parameningeal tumors. Positron emission tomography scanning may also be used to follow the course of disease in these children and is starting to replace radionuclide bone scanning as the primary mechanism to detect metastatic lesions. There are emerging data about the role of PET scanning in staging and therapy planning for Ewing sarcoma.

A biopsy of the lesion is necessary to establish the diagnosis. If possible, diagnostic tissue should be obtained from soft tissue rather than from cortical bone to reduce the potential for pathologic fracture.

Large tumors, primary tumors on the trunk and pelvis, and increased lactic dehydrogenase levels have been associated with worse prognosis, but they may be less important with current aggressive treatment regimens. Older age is associated with worse prognosis. The most significant prognostic indicators are tumor stage and size. The presence of metastatic disease is particularly relevant for prognosis. Metastatic

disease at the time of diagnosis is present in 20% to 25% of children. Isolated pulmonary metastases may be associated with a better prognosis than metastases to other sites, but this association is not confirmed. Histologic response also affects prognosis in that children who have marked tissue necrosis after chemotherapy have a better prognosis.

### Management

Approximately 75% of children who have Ewing sarcoma do not have identified metastases, but may have micrometastatic tumor. Therefore, local therapy alone (surgery or radiotherapy) is unlikely to be curative. Chemotherapy has made it possible to cure most patients who have localized Ewing sarcoma and has improved the outcome in children with metastatic disease.

The choice of radiation or surgery for local control is made based on the likelihood of preserving function. Functionally expendable bones should be removed. Aggressive surgical procedures, including limb-sparing excisions, are frequently performed. Some evidence suggests that complete surgical resection may improve prognosis. However, radiotherapy is required for local control and will improve the prognosis when resection with appropriate margins is not achieved or when the tumor is unresectable. Preoperative radiotherapy may also provide benefit. The local failure rate for children treated with radiotherapy on more recent protocols is 22.5%, with higher failure rates in children with central versus noncentral tumor sites. Children receiving radiotherapy are a negatively selected group with unfavorable tumor sites or size. Radiotherapy may also be helpful for treatment of pulmonary or osseous metastases.

Ewing sarcoma is extremely chemosensitive. Standard chemotherapy now includes vincristine, doxorubicin, and cyclophosphamide alternating with etoposide and ifosfamide. Studies have demonstrated the effectiveness

of these regimens for extraosseous Ewing and peripheral PNETs.

Dose intensity of the more active agents (cyclophosphamide and doxorubicin) has played a major role in improving disease-free survival. However, the outcome remains extremely poor for patients with metastatic disease. Additional chemotherapeutic agents, alone and in combination, and dose intensification are being studied for activity against Ewing tumors. Hematopoietic stem cell transplantation has also been used to treat high-risk Ewing tumors. However, the heterogeneous patient population and regimens make assessment of benefit difficult. Benefit may occur by using high-dose busulfan and melphalan, and allogeneic transplants may provide the additional benefit of a graft-versus-tumor effect as a result of an immune response to proteins derived from the characteristic gene fusion present in these tumors.

### Prognosis

Before the advent of multiagent chemotherapy, 85% of children who had Ewing sarcoma died within 2 years of diagnosis. Five-year, disease-free survival is approximately 75% for nonmetastatic disease, with event-free survival of 12% to 24% for children with metastatic disease. The outcome for children who experience relapse is very poor, with the small number of survivors usually among patients who experience relapse more than 2 years from initial diagnosis or those who experience relapse with lung metastases only.

### Follow-up

Children who have Ewing sarcoma require close follow-up for evidence of recurrent disease for at least 5 years from the time of diagnosis. Recurrences may occur later. Particular attention should be paid to the irradiated field of long-term survivors because second malignancies may arise (Table 225-6). Bone films should be obtained periodically. Children who have lower-extremity lesions whose growth is incomplete should be monitored for evidence of leg-length discrepancies, which may require arresting the growth in the opposite limb. Monitoring for potential late effects of the specific chemotherapeutic agents administered (eg, cyclophosphamide, doxorubicin) is important (see Table 225-4). Therapy-related myelodysplasia and acute myeloid leukemia (t-MDS/AML) are well-documented complications of alkylator therapy used in the Ewing sarcoma therapeutic protocols.

## OSTEOSARCOMA

Osteosarcoma is the most common bone tumor encountered in the first 3 decades of life. The incidence is 8.7 per million; about 400 patients are diagnosed per year in the United States. Osteosarcoma comprises 60% of malignant bone tumors. A male-to-female ratio of approximately 1.5:1 has been noted. The peak incidence occurs at age 14.5 years for boys and 13.5 years for girls, corresponding to the age of their growth spurts, although osteosarcoma can occur before puberty and after the adolescent growth spurt. Previous evidence that taller children are at increased risk has not been confirmed.

### Etiology

The hallmark of osteosarcoma is the production of osteoid or mature bone by proliferating malignant spindle cell sarcoma. The high incidence of this tumor in adolescents who are undergoing rapid skeletal growth, as well as individuals who have Paget disease of the bone, suggests that increased bone growth may play a role in the induction of the malignancy. Although children often report a history of trauma before the diagnosis, injuries most likely allow the recognition of an already-proliferating tumor.

Children at increased risk for osteosarcoma include those who have received irradiation to the bone, usually for the treatment of malignancy. Although radiation itself can be causative, children who have 1 tumor may be at increased genetic risk for a second primary malignancy. Children who have hereditary retinoblastoma and thus a constitutive deletion at *Rb*, the *Rb* tumor suppressor gene, have an increased incidence of osteosarcoma. Although one-half of these tumors occur within the radiation field, the risk for sarcoma is far greater, regardless of radiation exposure, because the abnormality at the *Rb* gene itself confers predisposition to osteosarcoma. Osteosarcoma in otherwise normal hosts also frequently involves mutation or loss of the *Rb1* gene, with inactivation of the tumor suppression pathway. Inactivation of *p53*, another tumor suppressor gene, is commonly detected in osteosarcoma. Germline mutations of this gene result in the Li-Fraumeni syndrome (an autosomal-dominant predisposition to multiple malignancies). Germline mutation of *p53* is present in 3% to 4% of children who have osteosarcoma. Many other chromosomal abnormalities have also been detected in osteosarcoma. As in many other malignancies in children, advances in genetic and molecular characterization are being pursued to understand tumorigenesis, to predict the behavior of disease, and to develop therapies to improve prognosis. No environmental risk factors for osteosarcoma have been identified.

### Clinical Manifestations

The presenting symptom in virtually all patients is pain. Palpable masses, swelling, and limited motion are common signs. Weight loss and other systemic effects such as anorexia are rarely seen; if these effects are present, then overt metastatic disease is likely. A few patients have fractures. Cough, chest pain, or dyspnea may occur with extensive pulmonary metastases, although most patients who have pulmonary metastases are symptom free. Ninety percent of tumors occur in the extremities; the metaphyses of bones are common sites of osteosarcoma origin. The lower extremities are involved most frequently, with approximately 60% of tumors occurring around the knee, 40% in the distal femur, and 20% in the proximal tibia. The sacrum, jaw, and phalanges are less commonly involved. Children who have Paget disease of the bone or those who have undergone radiotherapy in the area of the orbit may have osteosarcoma of the cranial bones.

The presenting symptom, bone pain, is ubiquitous and is commonly associated with trauma. Prolonged symptoms, or a history inconsistent with trauma,

**Table 225-6** Long-term Side Effects of Radiation

IRRADIATED AREA	RISKS	MONITORING
Cranium and nasopharynx	Cataracts Growth: impaired  CNS: learning impairment  Dentition: abnormal formation Thyroid: overt or compensated hypothyroidism High dose (>2,500 Gy): Hypothalamic dysfunction (decreased growth hormone; decreased gonadotropin, hyperprolactinemia) Hearing (especially with cisplatin) Hypoplasia of bone or soft tissues	Physical examination Growth charts (bone age, growth hormone, organ system function as appropriate) Monitoring of school function; neuropsychological evaluation Dental evaluation Free T <sub>4</sub> , TSH levels  — Growth; pubertal, menstrual, and fertility history (growth hormone, LH, testosterone, estrogen, prolactin levels) Audiogram Examination of area Dental evaluation
Neck and mandible	Dentition: abnormal formation, abnormal salivary function Thyroid: hypothyroidism Hypoplasia (includes impaired chest wall growth)	Free T <sub>4</sub> , TSH Examination of area
Thorax	Thyroid: hypothyroidism Lungs: fibrosis, decreased capacity  Cardiac: pericardial and valvular thickening; possibility of early myocardial infarction Breasts: impaired growth, possibility of increased malignancy Hypoplasia (including scoliosis)	Free T <sub>4</sub> , TSH levels History, pulmonary function tests, chest film baseline and as appropriate History, ECG, echocardiogram scheduled based on age, dose, and radiation exposure Breast self-examination, early mammograms start 8 yr after therapy or at age 25 yr Examination of area, radiograph of spine during puberty Liver function tests Serum creatinine, urinalysis protein (24-hr collection for creatinine, protein) Pubertal, menstrual, and fertility history, LH, follicle-stimulating hormone, estradiol or testosterone levels during puberty and if fertility is doubtful, semen analysis
Abdomen/pelvis	Liver (if in field) Kidneys (if in field)  Gonads (if in field)	Nutritional history Examination of area
Extremities	Gastrointestinal tract Hypoplasia	

CNS, central nervous system; ECG, Electrocardiogram; LH, luteinizing hormone; T<sub>4</sub>, thyroxine; TSH, thyroid-stimulating hormone.

For all patients, consider radiographs of bones every 5 to 10 years after ≥35-Gy radiation (risk for secondary malignancy). Examine skin for abnormal pigmented nevi (risk for second malignancy).

suggest the need for further diagnostic consideration. Bone abnormalities that may be confused with osteosarcoma include benign cysts, Ewing sarcoma, lymphoma, or tumor metastases. Table 225-5 provides the differential diagnosis of osteosarcoma involving the extremities.

### Evaluation

Radiographs of the involved bone show bony destruction with periosteal new bone formation. A sunburst appearance is characteristic, a result of the eruption of tumor through the cortex with subsequent formation of new bone. Soft-tissue swelling is often noted. Adequate histologic examination and analysis of biopsy samples are necessary to establish the diagnosis of osteosarcoma. The biopsy site is of critical importance, and the biopsy should be performed by an orthopedic surgeon with experience in oncology.

Osteoid found within a sarcomatous tumor is the characteristic histologic pattern. Osteosarcoma in

the child or adolescent is usually a high-grade tumor characterized by osteoblasts that demonstrate pleomorphism and bizarre mitoses. Necrosis, fibrosis, and calcification may be noted. This classic form usually arises from the medullary cavity. A less-aggressive form of osteosarcoma arises in the parosteal area of the bone and tends to spread along the shaft of the bone without invading the cortex. Periosteal, intracortical, and extraskeletal osteosarcomas have also been described.

Baseline lactic dehydrogenase and alkaline phosphatase levels should be obtained. The extent of the primary lesion is defined further by CT or, more frequently and preferentially, MRI. Approximately 20% of children will have metastatic disease identified at diagnosis. Metastatic disease in the lung should be sought by CT. Eighty percent of children with metastases will have pulmonary involvement. Bone scans can be helpful both for outlining the primary tumor and for detecting multiple primary lesions and

metastasis. Positron emission tomography scanning has become increasingly important in the staging, monitoring or response, response assessment, and aid in choice of treatment modalities.

### Management

When therapy of osteosarcoma was amputation of the affected limb, the natural history of disease was notable for the rapid appearance of pulmonary metastases 6 to 12 months after diagnosis, consistent with the presence of micrometastases at diagnosis. Five years after diagnosis, only 10% to 20% of children treated with amputation alone were alive. High-dose radiotherapy was even less effective than amputation. In the early 1970s, favorable responses to high-dose methotrexate with leucovorin and to doxorubicin were noted, and survival rates improved. A report of almost 50% survival after surgery alone attributed the better outcome to improved surgical techniques rather than chemotherapy. Adjuvant chemotherapy, therefore, was not suggested by many physicians until the 1980s, when studies confirmed the benefit of adjuvant chemotherapy. High-dose methotrexate, doxorubicin, and cisplatin are now considered standard therapy for osteosarcoma. Dose intensification and the role of other chemotherapy agents, including ifosfamide, etoposide, and carboplatin, continues to be investigated, both as front-line therapy and for patients whose disease responds poorly to initial therapy. International studies may facilitate addressing these issues. Targeted therapies, such as the use of trastuzumab (Herceptin), a monoclonal antibody against the epidermal growth factor 2 receptor, are also being studied. Addition of muramyl tripeptide to chemotherapy is being studied, and there are promising data showing it may enhance event-free survival and overall survival in children newly diagnosed with osteosarcoma.

The availability of effective chemotherapy and improved surgical technique made limb-sparing or subamputative therapies possible for many patients who have osteosarcoma. Survival after limb salvage is comparable to survival after amputation. Although the complication rate is higher, function is better. The portion of bone involved with tumor is removed and replaced by a prosthesis, a bone graft, or a composite. This procedure can be performed only if the vascular and neurologic integrity of the limb is not compromised. Preoperative chemotherapy may reduce the size of the mass enough to make such surgery possible. For lower extremity tumors, limb-salvage procedures were previously limited to children who had achieved most of their growth, but, currently, even younger children may be candidates. For children who have lesions of the humerus, any preservation of hand function will greatly improve quality of life.

For children in whom pulmonary metastases develop, surgical resection of these nodules may result in long-term survival, even if multiple surgeries are required. A similar approach has been used in patients found to have metastatic pulmonary disease at the time of diagnosis.

### Prognosis

Randomized studies have confirmed the role of adjuvant chemotherapy in improving the long-term,

disease-free survival of children who have nonmetastatic osteosarcoma. Approximately 65% to 75% overall disease-free survival can be achieved. The histologic response of the tumor to neoadjuvant chemotherapy has prognostic significance, with greater than 90% necrosis at the time of tumor resection resulting in improved overall outcome. Whether subsequent tailoring of therapy following poor necrosis achieves a better result than aggressive, early chemotherapy for all patients is unclear. The outcome after preoperative chemotherapy is similar or better than with immediate surgical excision. Preoperative chemotherapy improves the possibility of limb-salvage procedures by decreasing tumor size, and it allows early treatment of potential or demonstrated metastases. Preoperative chemotherapy also allows the assessment of tumor response to chemotherapy. The degree of tumor necrosis can be evaluated at the time of tumor resection and may help guide additional chemotherapy recommendations. Alkaline phosphatase level has also been shown to have independent prognostic significance. Other factors that may influence prognosis are related to the size and site of the tumor (children who have distal tumors may have better outcomes than those who have proximal or central-axis tumors) and the child's age (outcome improves with older patients). The most significant prognostic variable is the presence of metastatic disease. The presence solely of pulmonary metastases is associated with a better prognosis than bone metastases. Among children who have pulmonary disease, unilateral disease or fewer than eight nodules may carry a better prognosis, with survival in these groups of approximately 65% to 75%, compared with 25% to 35% for other patients with pulmonary involvement at diagnosis. The prognosis for patients with bone metastases at diagnosis or relapse is grim.

### Follow-up

Adjuvant chemotherapy has resulted in an increased number of long-term survivors of osteosarcoma. Virtually all children will have undergone either amputation or limb-salvage procedures. The hope is that less-disabling therapies will someday be feasible. Most of these children maintain a relatively normal lifestyle, including participation in various low-impact sports, but certain activities will be restricted. Long-term follow-up care includes imaging of the primary tumor site, bone scans, and chest CT scans performed semi-annually for 5 years and then at least chest radiographs annually until 10 years from the time of diagnosis to monitor for recurrent disease. Orthopedic evaluations and monitoring for late effects of the chemotherapeutic agents used (eg, doxorubicin, cisplatin, methotrexate, ifosfamide, etoposide) are also necessary.

## NON-HODGKIN LYMPHOMAS

Non-Hodgkin lymphoma (NHL) of childhood comprises a heterogeneous group of malignancies arising from lymphocytes and lymphoid precursors. The migratory nature of these cells is reflected by the variable sites at which the tumors occur and to which they spread. Recognition of the systemic nature of the disease, even in children who have only locally detectable

disease, has resulted in a marked improvement in survival rates. Childhood NHL is markedly different from adult NHL both in the immunohistopathologic types that occur and in the better survival rates noted in children. Current classification defines the following 4 main subtypes of childhood NHL: (1) lymphoblastic lymphoma, which comprises 30% of cases; (2) anaplastic large cell lymphoma (ALCL), 10% of cases; (3) Burkitt lymphoma, 40% of cases; and (4) diffuse large B-cell lymphoma (DLBCL), 20% of cases. Primary mediastinal B-cell lymphoma is now considered a distinct entity from mature B-cell lymphomas occurring in other sites. Other rare NHLs can also occur in children, including follicular lymphoma, peripheral T-cell lymphoma, mucosal-associated lymphoid tissue lymphoma, and post-transplantation lymphoproliferative disease.

Improved diagnostic techniques have resulted in emphasis on immunophenotype in diagnosis, staging, and treatment, with development of more tumor-specific treatment regimens. Burkitt lymphoma and DLBCL are both mature B-cell immunophenotypes with surface immunoglobulin. Lymphoblastic lymphoma is divided into precursor B-cell and T-cell immunophenotypes, the latter being the most common. Lymphoblastic lymphomas almost invariably express the enzyme terminal deoxynucleotidyl transferase demonstrating their more immature origins. Anaplastic large-cell lymphomas arise from T-cell lineage and generally have T-cell receptor gene rearrangements and *ALK* translocations. Advances in molecular techniques and gene profiling continue to provide insights into tumorigenesis and definition. These insights will affect development of therapies.

Lymphomas account for approximately 10% of childhood cancer; 60% of lymphomas are NHLs. The incidence of NHL is low in children younger than 5 years of age and then increases steadily throughout life. Non-Hodgkin lymphoma occurs more commonly in boys than in girls (2:1 to 3:1), with the greatest sex difference in Burkitt lymphoma, in which the male-to-female ratio is approximately 4.5:1. Non-Hodgkin lymphomas of childhood have a rapid growth rate, with the percentage of actively dividing tumor approaching 100% in some cases, and short doubling times that can be as few as 12 hours. They have a high frequency of dissemination, particularly to the bone marrow and CNS. Although the distinction between lymphoma and lymphocytic leukemia is defined by less than 25% versus more than 25% bone marrow lymphoblasts, respectively, the distinguishing biologic parameters are not clear.

### Etiology

The cause of childhood NHL is largely unknown. Immunodeficiency states, either congenital or acquired, are associated with the development of NHL, usually of the mature B-cell variety. Human immunodeficiency virus infection is associated with both NHL and Hodgkin lymphoma development and can be treated successfully if chemotherapy is used in combination with antiretroviral therapy. Lymphomas occur with increased frequency in children receiving immunosuppressive therapy following renal, cardiac, or bone marrow allografts.

Post-transplantation lymphoproliferative disease can sometimes be managed with withdrawal of immunosuppressive therapy alone, allowing reconstitution of the native immune system.

Epstein-Barr virus (EBV) infection may play a role in development of pediatric NHL, particularly in Burkitt lymphoma. Burkitt lymphoma of equatorial Africa almost always harbors EBV, compared with the North American variety, which does so only occasionally. The presence of EBV in lymphoma specimens suggests that viral infection may play a role in the development of NHL. A defect of T-cell regulation that permits the expansion of EBV-affected clones of B cells has been hypothesized to result in lymphomas, particularly in immunologically abnormal hosts.

Specific chromosomal aberrations have been described in Burkitt lymphoma, which place the *C-myc* oncogene adjacent to immunoglobulin heavy or light chain constant region genes. Cases of Burkitt lymphoma in equatorial Africa may have different breakpoints than cases outside of this area. Several specific, nonrandom chromosomal abnormalities have been reported in lymphoblastic lymphoma and large cell lymphomas.

### Clinical Manifestations

Seemingly localized lymphadenopathy is a common presentation of NHL, but locally advanced or disseminated disease is frequently found on evaluation.

Lymphoblastic lymphoma commonly involves supradiaphragmatic sites such as cervical, axillary, and mediastinal areas, or Waldeyer's ring. Dissemination to the bone marrow, the CNS, or the gonads is common in lymphoblastic lymphoma. Patients may also have skin or soft tissue involvement, particularly those who have B-lineage lymphoblastic lymphoma. B-lineage lymphoblastic lymphoma is more likely to be localized, and T-lineage lymphoblastic lymphoma is more likely to involve the mediastinum, CNS, or bone marrow. Lymphoblastic lymphoma is distinguished from lymphoblastic leukemia by percentage of bone marrow involvement, with lymphoma defined as less than 25% involvement. This distinction may be arbitrary, and research into biologic differences between lymphoblastic leukemia and lymphoma is ongoing. Children who have mediastinal masses frequently have a history of cough and, occasionally, acute respiratory distress. Because this malignancy advances rapidly, careful attention must be paid to the state of the airway because obstruction can occur during evaluation, even in children who have few symptoms, particularly with the administration of sedation. The obstruction may involve the lower airway, beyond the reach of an endotracheal tube, resulting in an inability to effectively ventilate the lungs.

Burkitt lymphoma and DLBCL can present with localized adenopathy or with a large abdominal or chest mass. An abdominal mass that may involve the ileocecal region, mesentery, ovaries, or retroperitoneum is seen in 30% to 40% of patients. Endemic Burkitt lymphoma in equatorial Africa frequently involves the facial bones. Anaplastic large cell lymphoma may produce peripheral adenopathy, although potential primary sites include the mediastinum and extranodal sites, including the tonsils, lungs, bone, testicles, and soft tissue.

Children whose disease is localized often feel well without systemic symptoms; those who have disseminated disease experience weight loss, fever, and malaise, as well as symptoms referable to the primary site of the disease.

The differential diagnosis of cervical adenopathy includes a variety of infectious and inflammatory processes. Malignant processes that cause enlarged cervical nodes include Hodgkin disease, neuroblastoma, leukemia, nasopharyngeal carcinoma, rhabdomyosarcoma, and thyroid carcinoma. Anterior mediastinal masses may be caused by T-cell leukemia or thymoma. Abdominal masses may be caused by constipation, splenomegaly, Wilms tumor, rhabdomyosarcoma, or neuroblastoma. Lymphoma is a rare type of primary bone tumor. Table 225-1, Table 225-2, and Table 225-3 provide differential diagnostic aids in evaluating patients who have NHL.

### Evaluation

The diagnosis of NHL should be established by pathologic evaluation of suspicious tissue. If adenopathy is present, then removal of the most suspicious node is suggested. Complete resection of the diseased area is not necessary because most NHLs in children are highly sensitive to chemotherapy. Frozen section and needle biopsies are discouraged to ensure proper diagnosis. The primary diagnosis is based on histologic findings and immunophenotyping by flow cytometry and immunohistochemistry. Gene rearrangement studies may be helpful. If possible, cytogenetic studies should be performed. A sufficient number of malignant cells may be present in bone marrow or pleural effusion fluid to establish the diagnosis without biopsy of the primary lesion. Use of polymerase chain reaction or other new techniques to identify morphologically inapparent bone marrow involvement may also be beneficial for prognosis and treatment decisions. For patients with a large mediastinal mass, biopsy may be contraindicated because of the risk for airway obstruction. In extreme cases, empirical treatment with corticosteroids or localized radiation to the mediastinum may be necessary before the diagnostic specimen is obtained. Alternative sites for obtaining diagnostic specimens must then be considered.

A lumbar puncture should be performed with cytocentrifugation of cerebrospinal fluid to detect meningeal involvement. Imaging studies should include a chest radiograph and a CT scan of the chest, abdomen, and pelvis in all patients. Bone scans and gallium scans can be helpful in selected patients, although PET scanning is being used with increasing frequency and may replace these modalities. The role of PET scans may be limited in staging, but is more important in evaluating response and monitoring for recurrence.

A variety of staging systems are used for lymphomas. The most common, the Ann Arbor system used for Hodgkin disease, is not of prognostic significance in NHL in children because of noncontiguous patterns of spread. The Murphy staging system is the most widely applied for NHL in children. Stage I disease indicates a single tumor, nodal or extranodal. Stage II indicates the involvement of 2 or more nodal or extranodal sites, both on the same side of the diaphragm.

Gastrointestinal tumors with only mesenteric nodes involved are also stage II. Stage III tumors involve both sides of the diaphragm, extensive abdominal disease, paraspinal or epidural tumors, or any primary intrathoracic tumors. Stage IV designates CNS or bone marrow involvement.

### Management

Most children who have NHL have disseminated disease at the time of diagnosis. Even clinically localized disease is not curable with localized surgery or radiotherapy alone. The choice of chemotherapeutic regimens is based on the clinical stage and the immunohistologic tumor subtype.

Lymph node biopsy is usually required for diagnosis and characterization of NHL. Removal of the tumor may be indicated only for patients who have Burkitt lymphoma whose tumor can be removed en masse (90%) with minimal morbidity. In general, major surgical procedures should be avoided because the healing time may delay initiation of chemotherapy, the most essential component of treatment.

The high incidence of micrometastatic disease at the time of diagnosis necessitates that all children who have NHL receive chemotherapy. Many agents are active in lymphomas. Optimal treatment regimens and strategies differ for patients with different subtypes of NHL; the histologic class of lymphoma predicts the efficacy of the regimens. Effective agents include cyclophosphamide, vincristine, prednisone, methotrexate, doxorubicin, cytosine arabinoside, etoposide, and ifosfamide. Children who have localized nonlymphoblastic lymphoma can be treated with short-course, low-intensity chemotherapy. Children who have localized lymphoblastic lymphoma require longer maintenance therapy. High-stage children with lymphoblastic lymphoma are treated with acute lymphoblastic leukemia-like protocols. Leukemia-like therapy may also be beneficial for children with ALCL. As new targeted therapeutic agents become available, treatment protocols are becoming more specific for each subtype of NHL. Rituximab, an anti-CD20 monoclonal antibody, may improve prognosis and allow dose decrease in standard chemotherapy for children with CD20-positive Burkitt lymphoma and DLBCL. The monoclonal antibody may work through mechanisms of direct cytotoxicity and chemosensitization. Other monoclonal antibody therapies are also being actively developed and investigated. Specific *ALK* inhibitors are being investigated for ALCL.

Relapsed or refractory mature B-cell NHL is extremely difficult to treat. Autologous or allogeneic stem cell transplantation is frequently recommended. Enrollment on novel therapeutic trials should be considered. Recurrent ALCL can be treated with single-agent vinblastine. Molecularly targeted therapies are also important considerations in the relapse setting.

Local control measures are rarely essential in the treatment of childhood NHL. Although lymphomas are radiosensitive, the use of radiotherapy does not improve survival in chemotherapy-responsive patients, and unnecessary morbidity may result. Radiotherapy is helpful in treating emergent situations, such as airway compromise or spinal cord compression, and for

treating overt meningeal involvement. Radiotherapy also plays a role in treating children who do not achieve a complete remission after standard chemotherapy or those who require bone marrow transplantation or palliative therapy.

### Prognosis

The prognosis is excellent for most children who have NHL, with more than 95% survival for those with localized disease and 80% to 90% survival for those with advanced disease, although subsets of children with worse prognosis can be found, including those with Burkitt lymphoma who have bone marrow and CNS involvement, those with mediastinal diffuse large B-cell lymphoma, and some patients with widespread anaplastic large cell lymphoma. Histologic findings are of prognostic significance for outcome, and they provide the basis for the choice of therapeutic regimen. Clinical staging is relevant because it is determined by a combination of the primary site, tumor burden, disease extent, and primary location. Age and sex may affect prognosis, even within histologic subtypes. Other prognostic factors include significantly elevated lactic dehydrogenase before therapy and, as with other malignancies, response to therapy. Investigations may permit evolution of treatment strategies to lower intensity of therapy for some patients, whereas new intensive chemotherapy or bone marrow transplantation regimens should improve the likelihood of survival in patients whose prognosis is poor or who experience relapse.

### Follow-up

Children who have NHL and are disease free 2 years from the time of diagnosis are usually cured. During this initial period, these children should be monitored for clinical symptoms and with complete blood cell counts, chest radiograph or CT scan, and evaluation of the primary site of disease. The follow-up of long-term survivors of childhood lymphomas should reflect the types of therapy (eg, cyclophosphamide, doxorubicin, methotrexate) administered (see Table 225-4).

## HODGKIN DISEASE

Hodgkin disease, or Hodgkin lymphoma, is a malignancy of the lymphoreticular system characterized by multinucleated giant cells, known as *Reed-Sternberg cells*, interspersed in an infiltration of normal-appearing cellular elements (lymphocytes, macrophages, histiocytes, plasma cells, and eosinophils). The Reed-Sternberg cells are the malignant cells of Hodgkin disease. Recent evidence supports a B-lymphocyte origin of the Reed-Sternberg cell with a cytokine-induced cellular infiltrate. Rare cases of clonal T-cell receptor gene rearrangements have been reported. The transformative steps that lead to the development of the malignant cell continue to be actively studied.

Hodgkin disease comprises approximately 6% of malignancies in children; about 600 cases are diagnosed in children in the United States each year. In developed nations, the incidence of Hodgkin disease exhibits 2 age peaks, one in young adults (15 to 30 years of age) and another in late adulthood. In

developing nations, the early peak occurs in preadolescence. Ten percent to 15% of the total incidence of Hodgkin disease occurs in children younger than 16 years. Hodgkin disease is extremely rare before the age of 5 years. A male predominance is present throughout the preadolescent age range; thereafter, the incidence is approximately equal in both sexes. Hodgkin disease in older teenagers and young adults is most common among whites.

### Etiology

The role of environment or genetics in the acquisition of Hodgkin disease is suggested by national and racial differences in the epidemiologic features of the disease. First-degree relatives of children who have Hodgkin disease have an increased risk for acquiring the disease, possibly because of genetic susceptibility or similar exposures (viral, environmental). Genetic risk is supported by a study demonstrating that monozygotic twins have a much higher concordance for disease development than dizygotic twins. Environmental factors that influence or delay exposure to common infection may play a role in the etiology of Hodgkin disease.

Epstein-Barr virus found in tumor DNA may reflect a causative role for the virus. Alternatively, patients may have an inappropriate immune response to this virus. Evidence of EBV infection is greater in certain subtypes of Hodgkin disease, that is, mixed cellularity, and may influence response to chemotherapy. The incidence of Hodgkin disease is known to be increased in patients who have certain underlying immunodeficiency diseases (eg, ataxia-telangiectasia, acquired immune deficiency syndrome).

### Clinical Manifestations

The most common presenting feature of Hodgkin disease is painless enlargement of the lower cervical lymph nodes. Approximately 50% of children who have this manifestation also have mediastinal disease. The classic pattern of spread is from the cervical lymph nodes to the mediastinum and then into the spleen and abdominal lymph nodes. Spread through the thoracic duct may result in disease of the right side of the neck and of the abdomen, without mediastinal involvement. Axillary or inguinal adenopathy or extranodal primary sites (eg, bone) are occasionally seen. Mediastinal disease is present in 76% of adolescents and 33% of 1- to 10-year-old children who have Hodgkin lymphoma. Pleural involvement occurs in approximately 10% of patients. Renal, skin, or nervous system involvement is less common. Constitutional symptoms related to Hodgkin disease occur in approximately one-third of patients at the time of diagnosis. The symptoms that predict a poor prognosis (*B* disease) are fever (oral temperature  $>38^{\circ}\text{C}$  [ $101^{\circ}\text{F}$ ]), weight loss ( $>10\%$  of body weight within 6 months), and drenching night sweats. Absence of these symptoms provides a better prognosis (*A* disease). Hematologic abnormalities may be present in Hodgkin disease (usually in advanced stages), even in the absence of bone marrow involvement. Hemolytic disease or the anemia of chronic disease associated with impaired mobilization of iron storage may occur. Neutrophilia in the absence of

infection occurs in approximately 50% of patients. Thrombocytopenia caused by immunologically mediated platelet destruction is also seen.

Lymphadenopathy occurs in children for various reasons, including infection (with bacteria, viruses, tuberculosis, atypical mycobacteria, and toxoplasmosis), malignancies (NHL, nasopharyngeal carcinoma, soft-tissue sarcoma, neuroblastoma), histiocytosis, and other inflammatory processes. A chest radiograph, a complete blood cell count, and a sedimentation rate should be obtained in any patient who has lymphadenopathy that is atypical for infection. Persistent lymphadenopathy, even after a transient response to antibiotic therapy, requires biopsy. Table 225-2 and Table 225-3 provide differential diagnostic aids in evaluating patients who have Hodgkin disease.

### Evaluation

Evaluation of the child who has a possible diagnosis of Hodgkin disease should begin with a complete history and thorough physical examination. Particular attention should be paid to B disease symptoms. Lymphatic areas to be evaluated include Waldeyer's ring and the cervical, supraclavicular, axillary, and inguinal lymph nodes. The sizes of the nodes found should be recorded carefully, and whether they are tender should be noted. In addition, a thorough abdominal examination should be performed, particularly to evaluate liver and spleen size. Retroperitoneal lymph nodes are not palpable. The blood cell counts may show anemia (caused by hemolysis or chronic disease), abnormal neutrophil count, or thrombocytopenia. Increase in the sedimentation rate, serum copper level, and ferritin level are probably related to cytokines induced by the tumor; they may be useful for monitoring response to therapy. Serum hepatic alkaline phosphatase isoenzyme levels may also be increased.

Radiographic evaluation of a patient who has a possible diagnosis of Hodgkin disease includes a chest radiograph and CT scans of the chest and abdomen. FDG-PET scanning is particularly useful for detecting disease in obscure sites and for monitoring response. Although bone involvement is rare, a bone scan should be considered in children who have advanced disease, particularly those who have bone pain or an increased serum alkaline phosphatase level. Bone marrow biopsies should be performed in all but those with stage IA or IIA disease.

The importance of defining subdiaphragmatic involvement is most clear when radiotherapy is the primary therapeutic modality. A staging laparotomy with splenectomy was used in earlier years to define the extent of necessary radiation. Improved imaging techniques and the use of chemotherapy in virtually all children and adolescents with Hodgkin disease obviate the need for staging laparotomy, thus preventing the risk for overwhelming bacteremia with polysaccharide-encapsulated organisms. Survivors of earlier eras who had splenectomy during childhood should have vaccines for pneumococcus, *Haemophilus influenzae* type b, and *Neisseria meningitidis* as recommended. Prophylactic antibiotics and empirical treatment for fevers are also necessary to limit risk.

The extent of disease spread is usually classified by the Ann Arbor staging system by means of either the clinical stage or the pathologic stage. The pathologic stage implies that the most extensive degree of involvement has been confirmed pathologically:

Stage I: involvement of 1 lymphatic region only

Stage II: involvement of 2 or more lymphatic regions on the same side of the diaphragm

Stage III: involvement on both sides of the diaphragm, including nodal regions, the spleen, or both

Stage IV: involvement of extranodal organs such as lungs, liver, bone marrow, kidneys, bone, or skin, in addition to lymph nodes

The Cotswold modification further divides stage III based on specific subdiaphragmatic nodal sites involved. In addition to symptom designation by A or B, it also adds a subscript X for bulky mediastinal disease and a subscript E for involvement of a single nodal site that is contiguous with a known nodal site of disease.

Four subtypes of Hodgkin disease are described by review of pathologic specimens. The nodular sclerosing subtype is distinctive because of collagenous bands that divide the lymphoid tissues into nodules and the presence of a *lacunar variant* of the Reed-Sternberg cell. It is the most common subtype in children, occurring in approximately 75% of adolescents and 40% of children younger than 10 years. The lymphocyte-predominant Hodgkin disease subtype is characterized by destruction of the lymph node architecture, with the cellular proliferation of benign-appearing lymphocytes. Reed-Sternberg cells are rarely found in the absence of fibrosis. This subtype is more common in young children; 33% of cases are in children younger than 15 years. Disease is usually localized. In the mixed-cellularity Hodgkin disease subtype, lymph node architecture is not preserved. Approximately 10 Reed-Sternberg cells are seen per high-power field, often with interstitial fibrosis; necrosis is not pronounced. It is more common in children younger than 10 years of age than in adolescents and is associated with high-risk disease. The lymphocyte-depleted Hodgkin disease subtype is characterized by the presence of fibrosis, necrosis, and abnormal cells (but only a rare lymphocyte). It is rare in children.

### Management

Hodgkin disease responds to radiation or chemotherapy. Protocols that use radiotherapy alone, chemotherapy alone, or both forms of therapy have all been successful, at least in some groups of patients. Choosing an appropriate therapeutic plan necessitates assessing the risk for disease recurrence and the potential risk for long-term ill effects in a particular patient.

Contiguous spread of Hodgkin disease by lymphoid organs allowed for success with radiotherapy alone. Full-dose radiotherapy (35 to 45 Gy) was standard therapy for adults with low-stage (I, II, and III) disease; chemotherapy is increasingly being used in this setting. When high-dose radiation was used, the involved fields, as well as 1 field beyond the area of proven disease, were treated. Skeletal and soft-tissue growth, particularly in the neck and clavicular areas,

are severely compromised when these doses of radiation are used in children. Cardiac and pulmonary complications, such as coronary artery disease, valvular disease, pneumonitis, or pulmonary fibrosis, occur as well. Low-dose radiotherapy (20 to 25 Gy) to involved fields only, and not extended fields, in conjunction with chemotherapy results in fewer and less severe late effects from the radiation.

Hodgkin disease is a chemotherapy-sensitive disease. The original chemotherapy agent combination that proved successful in the treatment of Hodgkin disease was mechlorethamine, Oncovin (vincristine), procarbazine, and prednisone (MOPP). In 1974, 10 years after the initial application of MOPP, the regimen of Adriamycin (doxorubicin), bleomycin, vinblastine, and dacarbazine (ABVD) was devised for the treatment of children who experienced relapse. The efficacy of this combination resulted in hybrid ABVD-MOPP regimens. MOPP is now rarely used because of significant long-term toxicity. Current protocols use a backbone of therapy with ABVE, prednisone, and cyclophosphamide (ABVE-PC) for treatment investigations, including the appropriate number of chemotherapy cycles for rapid and slow responders, appropriate additional chemotherapy regimens for children who do not have a good initial response, and the role of radiotherapy for patients who respond completely and rapidly to chemotherapy. Because cures with chemotherapy alone, even in higher stage disease, have been described, defining appropriate children who can avoid even the limited side effects of lower dose-involved field radiation will be important.

In the 1980s, combined modality therapy became the standard recommendation for younger patients who had not completed their growth and for those with advanced-stage disease, and it can play a role in patients with lower stage disease, even in mature patients. The advantages of combined therapies (chemotherapy and radiation together) include improved cure rates in patients with poor prognosis and reduction in the dose of radiotherapy administered to children so that skeletal development will proceed more normally. Chemotherapy also has side effects, including infertility after MOPP chemotherapy, cardiotoxic effects of the doxorubicin of ABVD, and pulmonary toxicity caused by bleomycin. Secondary leukemias have been described, particularly after the combination of MOPP and radiation. In choosing an appropriate regimen for a given child, the following must be considered: (1) the age and skeletal maturity of the child (likely effects on the developing child), (2) the extent of disease present (how much therapy is necessary), and (3) symptoms that might predict a poor prognosis. The response to initial therapy is also a significant factor in treatment decisions. Because so many regimens currently seem equivalent in terms of outcome, an investigational protocol should be used (if available) to help delineate the best treatment for patients in the future while ensuring appropriate treatment for those under study.

### Prognosis

Radiotherapy alone may cure up to 70% of children who have stage I or IIA Hodgkin disease and 50%

who have stage IIB or IIIA disease. The subsequent use of chemotherapy enables one-half of children who experience relapse after radiotherapy to be cured of the disease. However, single-modality treatment with radiation is not appropriate in children. Combined-modality therapy results in 5-year disease-free survival of approximately 90% to 100% for children who have localized disease and 80% to 90% for those who have high-risk disease. High-risk features include advanced-stage disease, a large mediastinal mass, more than 4 sites of involvement, and B symptoms. In children whose disease progresses or relapses, cure may be accomplished with intensive chemotherapy and radiation or with stem cell transplantation. Salvage rates of more than 60% are reported, with children whose diseases progress while they are receiving therapy having a poorer prognosis than those who experience relapse after treatment.

### Follow-up

Children who have Hodgkin disease should be monitored for evidence of recurrent disease for as long as 10 to 15 years after the original diagnosis. In addition to a thorough physical examination, useful tests for prolonged follow-up include a complete blood cell count, a sedimentation rate, and a chest radiograph.

After high-dose radiotherapy to the neck and mediastinum, soft-tissue and bone growth abnormalities include shortening of clavicles and underdevelopment of the soft tissues of the neck. Sitting height decreases after radiation to the axial skeleton in proportion to the growth potential remaining at the time of radiation. In prepubertal girls, breast development may be impaired. The incidence of breast cancer may be increased after chemotherapy and irradiation, particularly for girls who received radiotherapy in early adolescence during breast tissue proliferation. Patients should undergo annual mammographic examinations beginning 8 years after therapy or at age 25 years.

Overt hypothyroidism (low thyroxine and increased thyroid-stimulating hormone [TSH]) occurs in approximately 5% to 10% of patients who undergo irradiation, whereas compensated hypothyroidism (increased TSH and normal thyroxine [ $T_4$ ]) occurs in 50% to 90% of such patients. Thyroid function should be assessed for at least 15 years. Thyroid replacement therapy is suggested when the TSH level is increased.

Children who receive mediastinal irradiation may have pulmonary fibrosis with variable abnormalities detected by pulmonary function testing. Late cardiac abnormalities include pericardial thickening and, occasionally, valvular dysfunction. Early myocardial infarctions have been reported. These toxicities may be exacerbated by the use of bleomycin and anthracyclines.

Fertility in women is affected by the use of radiation and chemotherapy. Pelvic irradiation of a woman causes infertility unless oophoropexy (moving ovaries to the midline) is performed. After oophoropexy, all teenaged girls treated with radiation alone and 88% of those treated with combined-modality therapy maintained normal menses. Women older than 30 years of age experience ovarian failure after treatment with MOPP more frequently than do younger women. All

women should be advised of the possibility of early menopause. A menstrual history should be elicited at each visit.

Testes are more severely affected by cytotoxic therapies than are ovaries. Fortunately, the radiation fields used in Hodgkin disease spare the gonads in male patients. Six courses of MOPP chemotherapy, however, always result in male sterility. Approximately 50% of patients treated with 3 courses of MOPP are sterile. ABVD causes less impairment of spermatogenesis, and current regimens also carry less risk. Men interested in fathering a child may consider sperm banking, post-therapy monitoring of gonadotropin levels, and semen analysis. Recovery has been documented in previously sterile men.

Acute myelogenous leukemia occurs in patients who survive Hodgkin lymphoma at the rate of approximately 1% per year for the first 10 years after treatment with MOPP and radiotherapy. Thereafter, the risk seems to decrease. The incidence is lower with single modality therapy or after ABVD and radiation, and the risk is expected to be lower with current therapy. Other solid tumors in addition to breast cancer may occur after treatment for Hodgkin lymphoma, including thyroid cancer, bone tumors, and NHL.

Children who had a splenectomy are at risk for overwhelming infection, particularly by encapsulated organisms. Empirical treatment with intravenous antibiotics is recommended for fever ( $>101^{\circ}\text{F}$  [ $38^{\circ}\text{C}$ ]) in these children.

## GENERAL ONCOLOGIC CARE

### Referral to a Pediatric Oncologist

Fortunately, children who have malignancies represent a very small proportion of patients in a general pediatric practice. The treatment of such children is highly specialized. Often, the evaluation and management of these patients needs to happen very rapidly. Proper care begins with referral to a pediatric oncologist, even if the initial procedure indicated is surgical. The pediatric oncologist will coordinate care with appropriate surgical and diagnostic radiology.

Recognition of potential malignancy in the differential diagnosis of a child's presentation is essential to ensure that inappropriate therapy will not be administered—for example, corticosteroids should not be provided to a patient whose symptoms mimic EBV infection or reactive airway disease. For many tumors, appropriate baseline studies must be obtained before surgical procedures are instituted. For example, AFP and hCG levels decrease rapidly after removal of a germ cell tumor, as do catecholamine levels after removal of a neuroblastoma. Delayed assays for such markers may result in an inability to recognize an important indicator of recurrent disease in a given patient. The chest CT scan should be performed before surgical procedures are performed because perioperative atelectasis may interfere with the detection of metastatic disease in the pulmonary parenchyma.

The tumors of childhood often behave differently from those of adults, even when histologically

identical. In addition, children tolerate radiation and chemotherapy differently than adults. Therefore, all children should benefit from the care of a pediatric oncologist. Services available for children and their families at pediatric referral hospitals often ease the burden of being diagnosed with a life-threatening disease. Pediatric social workers, child life workers, and nurses experienced in dealing with children and adolescents who have cancer are available. For children living at a distance from a center, initiating therapy at a referral medical center and administering a portion of the subsequent treatments and evaluations closer to the child's home are often possible. At times, a local oncologist can assist in administering chemotherapy to children living at a distance from a center; however, such oncologists should not choose a therapeutic regimen or evaluate major problems that may arise without corroboration with the pediatric oncologists at the referral medical center. Several excellent resources are available for children, families, and care physicians, including CureSearch ([www.curesearch.org](http://www.curesearch.org)), a component of the COG. The American Cancer Society and National Cancer Institute also have Web sites with beneficial information oriented to the care of children. Adolescents and young adults are a special group within the practice of pediatric oncology, in which most patients are young children. The official COG Web resource for this population is available at [www.teenslivingwithcancer.org](http://www.teenslivingwithcancer.org), a component of Melissa's Living Legacy.

Several oncologic emergencies exist that general primary care physicians must recognize. Cord compression may result from neuroblastoma, Ewing sarcoma, lymphoma, or any other tumor that invades the spinal canal. Such children experience incontinence, loss of reflexes in the lower extremities, or decreased ability to use the lower extremities. Rectal sphincter tone may be decreased. Rapid institution of therapy may reverse such findings, markedly changing the long-term functioning of the patient. Thus, recognition of such findings should prompt immediate referral to a pediatric oncologist, who, in conjunction with a neurosurgeon or radiation therapist, will be able to deliver emergent therapy.

Children whose bone marrow is infiltrated by leukemia, Ewing sarcoma, neuroblastoma, or lymphoma may have pancytopenia and thus be at risk for infection as a result of neutropenia, bleeding caused by thrombocytopenia, and congestive heart failure as a result of anemia. Rapid lysis of cells (tumor lysis syndrome) because of the high cell turnover rate of the tumor itself (as is seen in Burkitt lymphoma) or to cytotoxic therapy is characterized by increased uric acid (risk for urate nephropathy), hyperkalemia, hypocalcemia, and hyperphosphatemia. Medical management includes allopurinol or urate oxidase, urinary alkalization, and binders of potassium and phosphate. Dialysis may be necessary. If delayed arrival to the medical center is anticipated, allopurinol should be started by the referring physician when a tumor that has a large cell burden (eg, leukemia, Burkitt lymphoma, and bone marrow involvement with either neuroblastoma, Ewing sarcoma, or rhabdomyosarcoma) is suspected.

Primary care physicians should recognize the signs and symptoms of superior vena cava syndrome, which may include swelling, plethora, and cyanosis of the face, neck, and upper extremities; engorged vessels; cough and wheezing; chest pain; headache; diaphoresis; and visual changes. Lymphomas and other malignancies are the leading causes of superior vena cava syndrome, which may progress rapidly enough to be life threatening. Therefore, prompt recognition of the potential for mediastinal mass as the cause of the symptoms and appropriate referral is essential.

### **Role of the Primary Care Physician During Therapy**

The most prominent toxicity that results from chemotherapy is myelosuppression. Infections in children with neutropenia can rapidly result in septic shock, particularly if gram-negative organisms are involved. Primary care physicians who monitor these children can help by recognizing the risk of fever and immediately referring the patient to the pediatric oncologist when he or she becomes febrile. If the center is at a distance, then the primary care physician becomes the front-line caretaker, obtaining proper culture specimens and initiating antibiotic therapy (usually an aminoglycoside and semisynthetic penicillin or a fourth-generation cephalosporin). In such circumstances, the primary care physician should discuss aspects of care with the pediatric oncologist to ensure that all appropriate measures are taken. Many children receiving intensive chemotherapy have indwelling central venous catheters that increase the risk for septicemia with gram-positive organisms. These children, even in the absence of neutropenia, should have blood drawn for culture, and therapy with antibiotics should be considered if fever develops. Any person who is febrile and had a splenectomy should be given antibiotics empirically to treat potential infections with polysaccharide-encapsulated organisms. In the absence of splenectomy and a central line, treatment of children whose blood cell counts are normal is usually similar to that of a healthy child. The primary care physician can see such children for common pediatric complaints, including skin rashes, earaches, and respiratory and gastrointestinal infections because these children seem to handle such infections without undue difficulty. Varicella, however, is a major threat to all immunocompromised children because dissemination of disease is likely even in the absence of neutropenia. Before the availability of acyclovir and the varicella vaccine, significant morbidity and mortality occurred in such children. Immunocompromised children who are exposed to varicella by a sibling or a close playmate should receive varicella-zoster immunoglobulin (VZIG) within 4 days of the exposure. If Varicella-zoster immunoglobulin is not available, patients can be treated with prophylactic antiviral therapy such as acyclovir or sometimes with general immunoglobulin. If active varicella disease occurs, then the patient should be treated with acyclovir or related new-generation antiviral drugs, often as an inpatient. Chemotherapy is usually withheld during the treatment of varicella.

Children who are receiving treatment for a malignancy should continue to see their primary pediatrician for well-child visits. This effort is in anticipation of their ultimate successful treatment and cure. Immunizations are delayed until 1 year after therapy is terminated because live vaccines may cause disease, and inactivated vaccines rarely result in a normal immune response. An exception is made for the inactivated influenza vaccine and not the live virus influenza vaccine. This treatment may be performed by the oncologist, but may also be requested of the pediatrician. In addition, the child's family should be immunized. The pediatrician should remain involved in continuing developmental issues that are, at times, exacerbated by the treatment of a malignancy. With the current success rates in treating children who have cancer, pediatricians should anticipate the return of these children to their practice for most of their care. When children with cancer do not survive, the pediatrician also has an important role in continued care of the family, particularly the siblings. Therefore, maintaining a relationship with the patient and family is essential.

### **Integration of Palliative Care**

Children with cancer often experience distressing symptoms and side effects throughout the course of their disease. Early involvement of palliative care principles and providers can assist with symptom management related to cancer presentation, therapy toxicities, and progressive disease. Pediatric palliative care can also support psychosocial, spiritual, and emotional adjustment and coping as well as provide support through illness from diagnosis to death or survival. When necessary, palliative care will include grief counseling and bereavement issues. Although important for all families living with childhood cancer, palliative care may be particularly important for those with an overall poor prognosis. Palliative care providers will work closely in collaboration with pediatric oncologists and the multidisciplinary psychosocial support team.

### **Care of Long-term Survivors**

Children treated for malignancy have, for the most part, received several extremely toxic agents, the long-term implications of which are not known in their entirety. Studies of a new treatment regimen's late toxicities are often in their early stages, and, as therapy evolves, so do the potential late side effects. Children should continue to return at least annually to the treating institution or to a similar institution elsewhere to be monitored for potential side effects and to be informed of problems occurring in patients treated similarly. Many factors, including patient preference, aging out of pediatric facilities, and distance, will result in the primary care physician becoming the central figure in ensuring that children undergo appropriate follow-up. Knowledge of late effects and appropriate screening is essential, as is understanding the heterogeneity of treatment, the differences in regimens from different eras, and the variability in toxicities experienced by patients treated with similar

regimens. Toxicities of currently used chemotherapeutic agents and of radiation to particular areas are listed in Table 225-4 and Table 225-6, respectively, and follow-up studies are described. The COG has developed long-term follow up guidelines (available at [www.survivorshipguidelines.org](http://www.survivorshipguidelines.org)).

Multidisciplinary clinics, which evaluate all survivors for potential late effects, are being formed in some hospitals. Subclinical evidence of cardiac damage after anthracycline administration and of pulmonary toxicity (decreased diffusing capacity) after bleomycin administration is found in some survivors. The course of the toxicity is not clear, but evidence has been found for progression of cardiac abnormalities. The long-term effects on renal function and hearing are not yet known. Fertility has been impaired in some adolescent patients who received alkylating therapies, but the incidence of this dysfunction is lower than in adults treated similarly. Radiation to the gonads also causes infertility. Affected women need hormone replacement for feminization and to prevent the osteoporosis associated with estrogen depletion. Testosterone levels in treated male subjects usually remain in the normal range, but they should be monitored. Endocrine dysfunction after radiation may involve the thyroid, hypothalamus, and pituitary. Studies of the mechanism of impairment may help in treating other affected patients more effectively. Thyroid radiation often causes compensated (increased TSH, normal  $T_4$ ) or overt (increased TSH, decreased  $T_4$ ) hypothyroidism and should be treated with thyroid hormone therapy.

Secondary malignancies are reported in long-term survivors. Mutagenic agents such as mechlorethamine, cyclophosphamide, etoposide, and radiotherapy play a role. A genetic predisposition to malignancy exists for patients who have certain disorders (eg, bilateral retinoblastoma).

Neurocognitive function and school performance will be affected in many children who are going through or who underwent treatment for childhood cancer. Education specialists, pediatric oncology nurse practitioners, or persons from both fields can be extremely helpful to the child and the child's teachers by explaining the child's diagnosis and treatment to school administrators and teachers, and, when appropriate, to classmates; defining the problems and limitations the child will have in keeping up with schoolwork during periods of intensive treatment; and providing or arranging (through the school system) for lessons and special tutoring during prolonged hospitalizations and recovery periods at home.

The psychosocial effects of childhood cancer also differ from child to child. Some children were so young when they received treatment that they do not remember the ordeal; others were unable to participate in normal childhood experiences because of their illness. Some children have no physical deficits; others have permanent deformities (eg, amputations, scoliosis, hair loss, scars). Despite these issues, most survivors rate their health as good. Most children are emotionally intact people who are able to live and work normally within mainstream society, although mental health impairment is reported by survivors across the

diagnostic spectrum. Unfortunately, certain workplaces and insurance companies continue to discriminate based on a history of cancer. Businesses and agencies must be taught to accept people who are cured and are likely to have a normal future. Legal protection is available to survivors through the Americans With Disabilities Act, and advocacy resources exist at both the community and national level.

Pediatricians must be advocates for these successfully treated people. Past medical conditions that will not interfere with future health should not be a barrier to success. Furthermore, pediatricians must remain aware of potential late effects of therapy. Screening for toxicities will allow for interventions that can maintain health.

## Chapter 226

# CEREBRAL PALSY

Nancy Murphy, MD

Cerebral palsy (CP) is a clinical descriptive term for a continuum of disorders of the development of movement, posture, and coordination caused by nonprogressive disturbances affecting the brain in its early development (fetal, infantile, and early childhood). The motor disorder is often accompanied by a combination of disturbances of sensation, cognition, communication, perception, or behavior or by a seizure disorder, contributing further to activity limitation and restricted participation. Most children with CP develop some impairment of form or function in the musculoskeletal system. The most common impairments are contractures (eg, equinus deformity), torsional changes in long bones (eg, femoral and tibial torsion), and joint instability (eg, hip displacement).

### EPIDEMIOLOGIC FEATURES

With a prevalence of 3.6 per 1,000, more than 100,000 children in the United States have CP. Although some variation has been described, the incidence has generally remained stable over the past 20 years. CP is more common with lower birth weight and with younger gestational age at birth. For instance, among 1,812 infants born before 33 weeks' gestation, CP was diagnosed at 5 years of age in 159 children (prevalence 9%).

Cerebral palsy affects body structures and function, as well as activities and participation. Among children with CP, 8% have an autism spectrum disorder and 35% have epilepsy; 56% are able to walk independently, while 33% have limited or no walking ability. Children with CP have longer average hospital stays (6.3 vs 4.1 days), have more diagnoses (5.6 vs 3.0), and undergo more procedures (1.7 vs 1.1) than children without the disorder. The risk for CP is higher in infants of very low birth weight and those from multiple pregnancies. CP in preterm infants is associated most commonly with periventricular leukomalacia, with or without severe periventricular bleeding or infarction. An increasing proportion of infants from both of these groups survive into childhood. The biggest challenge to the prevention of CP remains the prevention of prematurity. A recent study found that the prevalence of CP in very low-birth-weight infants and those born at less than 32 weeks' gestation decreased from 6% of live births in 1980 to 4% in 1996. This improvement occurred despite an increase in live births at very low birth weight, a decrease in neonatal deaths, and an increase in multiple births.

### ETIOLOGY

A definite cause cannot be identified for many cases of CP, but when a cause can be identified, it is usually of prenatal origin. Intrapartum events play a limited role. Neither sophisticated fetal monitoring nor a higher

rate of cesarean deliveries has reduced the occurrence of CP. Isolated risk factors, such as fetal bradycardia, neonatal acidosis, intraventricular hemorrhage in the absence of periventricular leukomalacia, and low Apgar scores taken in isolation, are poor predictors of CP, especially in full-term infants. However, low birth weight (2,000 g or less), periventricular leukomalacia (necrosis of white matter near the lateral ventricles), hydrocephalus, congenital malformations, and newborn encephalopathy (recurrent seizures, hypotonia, coma) are all associated with CP. Prenatal maternal chorioamnionitis has been shown to increase significantly the risk for CP in both term and preterm infants. In approximately 10% of children who have CP, the cause of the condition is thought to be post-neonatal (after 28 days). Causes include infections (eg, meningitis, encephalitis), asphyxia, and accidental injury. In some instances, CP may be prevented by reducing the occurrence of injuries during childhood and by minimizing periventricular leukomalacia in premature infants through improving circulation and countering the effects of excitatory neurotransmitters (eg, head cooling in the newborn who has had a hypoxic or ischemic event). The timing of the insult to the brain may affect the manifestations of CP. For example, disturbances occurring between 24 and 28 weeks' gestation are more likely to produce spastic diplegia or tetraplegia (quadriplegia), whereas those occurring at term are more likely to produce dyskinesia.

More recently, there is increasing evidence to suggest that multiple genetic factors contribute to the etiology of CP. For example, noncerebral congenital anomalies are more prevalent in children with CP than in typical children; there is a higher concordance rate for CP in monozygotic twins than in dizygotic twins; and higher than expected recurrence rates of CP syndromes in families support a genetic etiology.

### CLASSIFICATION AND DIAGNOSIS

CP may be classified according to the type, distribution, and severity of motor abnormality (Box 226-1). This classification system can be simplified into the following 3 categories: spastic (involving the pyramidal tracts), dyskinetic (involving the extrapyramidal tracts), and mixed (involving both). Spasticity is defined as velocity-dependent passive resistance of muscle to stretch. It is associated with neurologic signs that include hyperreflexia, clonus, extensor

#### BOX 226-1 Classification of Cerebral Palsy

- Spastic
  - Diplegic
  - Quadriplegic
  - Hemiplegic
- Dyskinetic
  - Choreoathetotic
  - Dystonic
  - Ataxic
- Mixed

plantar response, co-contraction of muscles, persistent primitive reflexes, and abnormal postural control. These abnormalities impair normal movements, such as gait and the manipulation of objects, in complex ways. Movement is often described as stiff, and patterns of movement, such as fisting of the hands, retraction of the shoulders, scissoring of the legs, and toe-walking, are often abnormal. Although most attention has been focused on the extremities, evaluating the trunk is important as well. Hypotonia of the trunk and neck is common, as are impairments that affect function in a child who has spastic quadriplegia.

In diplegia, the legs are affected, with relative sparing of the arms. In quadriplegia, all 4 limbs are involved. In hemiplegia, only 1 side is involved, with the arm usually more impaired than the leg. In extrapyramidal CP, the impairment is diffuse, with marked discoordination and the presence of involuntary activity. Dyskinesia includes the involuntary movements of athetosis and chorea, which are most pronounced when the child initiates a movement, as well as dystonia. Dystonia is characterized by sustained muscle contractures that lead to abnormal posture and twisting of the limbs. Dysarthria commonly occurs with dyskinesia. Ataxia involves incoordination of movement and impaired balance and may be associated with an intention tremor. Because the fibers in the corticospinal tract that control the legs are closest to the ventricles, any periventricular injury is likely to lead to spastic diplegia. This condition most commonly occurs with hypoxic-ischemic injury in a preterm infant between 28 and 36 weeks' gestation, in which the periventricular area is most susceptible to injury because of immature cerebral vascularization. This injury is often characterized by subsequent enlargement of the ventricles or development of periventricular leukomalacia. Children of any gestational age with hydrocephalus are also more likely to develop spastic diplegia. Generally, children who have spastic quadriplegia have more generalized and extensive lesions, and they are more likely to have intellectual disabilities (64% have an IQ below 50) and seizures (56%) than children who have other kinds of CP. Children who have spastic quadriplegia are also more likely to have feeding difficulties, severe joint contractures, and scoliosis. Children with extrapyramidal CP frequently have problems with feeding and communication because of oral-motor discoordination. The most common system for classifying the severity of CP is the Gross Motor Function Classification System (GMFCS), a 5-level system to classify severity of motor involvement in children with CP based on their functional abilities and their need for assistive technology and wheeled mobility.

Each form of CP can be caused by a multitude of conditions, and a single etiologic factor (eg, meningitis) can lead to different forms of CP. Therefore, a direct link between the type of CP and its cause (when a cause can be found) cannot be established without using diagnostic evaluations such as cranial ultrasonography or magnetic resonance imaging (MRI). Additionally, chromosomal disorders and inborn errors of metabolism can be misdiagnosed as atypical CP, and genetic evaluations may be diagnostic when the CP remains unexplained.

## EARLY AND DIFFERENTIAL DIAGNOSIS

Although the brain lesion or anomaly that was recognized in early childhood is no longer progressive, the clinical manifestations of CP change over time, especially in the first several years of life. Abnormal patterns emerge as the damaged nervous system matures. For example, the child who is destined to have spastic quadriplegia will often be hypotonic in early infancy. At 6 months of age, as tone increases, the child may develop adduction of the thumb (palmar thumb) followed in 1 to 2 months by scissoring of the legs when held upright. By 9 months of age, the child may have diffuse spasticity and hyperactive deep-tendon reflexes. Dyskinetic patterns may not be obvious until approximately 18 months of age. Ataxia may not be apparent until even later. In a study of 1,726 children from 5 urban school districts, the mean age at which CP was diagnosed was 10 months. Therefore, in addition to the formal developmental screening recommended for all children, those at risk for developing CP should have regular careful physical examinations, with special attention paid to their neurologic status.

Early diagnosis of CP is aided by a history of an abnormal pregnancy, labor, delivery, or neonatal period or by the occurrence of a serious acute illness and trauma. The diagnosis is further aided by evaluating the child's primitive reflexes (eg, the asymmetrical tonic neck response), postural responses (righting the head when tilted to the side), muscle tone, motor milestones, and neurobehavioral responsiveness. Persistent or exaggerated primitive reflexes, a delay in the emergence of postural reactions, hyperreflexia, asymmetry, and abnormal muscle tone all suggest the possibility of CP. Other early signs that suggest CP include difficulty feeding because of abnormal oral-motor patterns (tongue thrusting, tonic bite, oral hypersensitivity), irritability, and delayed milestones such as head control. Children with CP may benefit from timely referral to formal early-intervention programs, which are mandated under the Individuals with Disabilities Education Act (IDEA).

A diagnosis of CP implies that the neurologic process is not progressive and that the disorder is in the brain. The differential diagnosis includes neurodegenerative disorders, inborn errors of metabolism, developmental or traumatic lesions of the spinal cord, severe neuromuscular disease, movement disorders, spinocerebellar degeneration, neoplasms, hydrocephalus, and subdural hematoma. Repeated examinations are necessary to rule out a progressive degenerative condition. Recurring subclinical seizures or adverse reactions to anticonvulsants may worsen the clinical condition of children who have CP. Hypotonia in association with weak muscles and depressed tendon reflexes suggests a neuromuscular disease, although many children with both spastic and extrapyramidal CP are hypotonic in early infancy. Extrapyramidal signs in early infancy or marked worsening during periods of illness also make the diagnosis of CP a possibility. If a child diagnosed as having dyskinetic CP has symptoms that worsen significantly as the day progresses, dopa-responsive dystonia should be considered. This rare but treatable form of dystonia may begin with toe-walking and difficulties with gait; it

responds dramatically to administration of levodopa. In most instances, no history can be found of a pre-existing condition that would be consistent with CP. Other rare inborn errors of metabolism, such as arginase deficiency and glutaric aciduria, may mimic CP. However, these conditions cause progressive deterioration, whereas CP does not. If a child has a parent who has CP and has late-onset spastic diplegia with no preceding history of prenatal or neonatal problems, then hereditary spastic diplegia may be the cause.

### ASSOCIATED DISORDERS

Table 226-1 lists disabilities and impairments associated with CP. All types of language impairments may be encountered, from aphasia to disorders of

articulation. Speech impairments may be related to hearing, intelligence, experience, language development, the integration of motor mechanisms of the oropharynx, and coordination of breathing patterns. Nearly 75% of individuals who have CP are cognitively impaired. Approximately 40% have learning disabilities, 35% have epilepsy, 20% have visual impairments, and 9% have infantile hydrocephalus. In persons who function in the normal range of intelligence, specific learning disabilities, such as visual-spatial impairment, are common. Impaired mobility is also common and may result from spasticity with or without joint contractures and scoliosis. Self-care and hygiene may be impaired by gross-motor and fine-motor abnormalities and associated conditions, such as drooling. Impairments in gastrointestinal functioning include

**Table 226-1**

### Disabilities and Impairments Associated With Cerebral Palsy in Children and Possible Interventions

DISABILITY OR IMPAIRMENT	POSSIBLE INTERVENTION	POSSIBLE CONSULTATION
Impaired communication	Augmentative communication aids	Speech therapist, audiologist
Impaired cognition	Early intervention, special education program, formal educational testing	Education specialist, psychologist, school advocate
Weakness or impaired mobility	Orthoses (braces), walker, wheeled mobility and strength training, hippotherapy Constraint therapy for hemiplegia	Orthopedist, orthotist, physiatrist Physical therapist specialty program, gait laboratory Hippotherapist Occupational therapist
Spasticity	Medications, selective dorsal rhizotomy, intrathecal baclofen, botulinum toxin injections	Orthopedist, neurodevelopmental specialist, physiatrist, neurologist, neurosurgeon
Joint contractures	Range of motion, orthoses, surgery	Physical therapist, orthopedist, orthotist
Scoliosis	Orthoses, surgery	Orthopedist, orthotist
Impaired self-care and hygiene	Assistive technologic devices, home modifications, training	Occupational therapist, rehabilitation engineer
Drooling	Scopolamine patch, glycopyrrolate, surgery, botulinum toxin injections, acupuncture	Otolaryngologist, acupuncturist
Sexual functioning	Education, adaptive devices	Gynecologist, urologist, psychologist
Impaired nutrition or feeding	Education, monitoring, medical evaluation, medication, enteral routes of feeding	Dietitian, gastroenterologist, speech therapist, occupational therapist, surgeon
Dental caries, malocclusion	Repair of dental caries, orthodonture	Dentist, pedodontist, orthodontist
Seizures	Medication, surgery	Neurologist, neurosurgeon
Impaired vision or hearing	Assistive devices, surgery	Ophthalmologist, otolaryngologist
Impaired access to care	Financial counseling, care coordination, transportation	Financial counselor, care coordinator, specialty program
Adverse effects on family	Parent support group, counseling, support, respite	Social worker, psychologist, specialty program, care coordinator
Impaired transition to adulthood	Counseling, adult-oriented health care, care coordination, transportation, recreation, vocational services, financial planning, guardianship	Internist, family physician, care coordinator, vocational specialist, independent living specialist, attorney, psychologist, financial planner

drooling (31%), dysphagia (19%), and constipation (25%). In general, physical growth is inhibited, and osteoporosis is common in patients with severe quadriplegia and immobility. Many of these children fail to thrive, especially those who have dyskinesia or spastic quadriplegia. Feeding difficulties caused by oropharyngeal incoordination, gastroesophageal reflux, and recurrent vomiting occur and may be associated with aspiration. Dental disease (malocclusion and dental caries) is common. Seizures are common, as are impaired vision and hearing. Behavioral problems are 5 to 8 times more likely to occur in children who have CP than in their uninvolved peers, especially in those who have hemiplegia. Sociocultural risk factors have a profound effect on development and interact with biologic risk factors. Perinatal and other biologic risk factors can lead to intellectual impairment.

## EVALUATION

Neuroimaging techniques such as ultrasonography, computed tomography, and MRI have increased physicians' understanding of the structural abnormalities associated with CP and may help clarify the timing of a lesion. Neuroimaging may demonstrate periventricular leukomalacia, postischemic necrosis, cerebral dysgenesis, hydrocephalus, porencephaly, tumor, prenatal ischemic injury, or leukodystrophy. The information gained with brain imaging can confirm the diagnosis of CP and can be useful to the physician in explaining (or demonstrating) the specific cause of a child's CP to the parents. The electroencephalogram is an important part of the diagnosis and management of associated seizures, but is not helpful in the diagnosis of CP; continuous electroencephalogram monitoring with videography may help differentiate seizures from other movement disorders. The presence of dysmorphic features may trigger a search for a chromosomal abnormality or a genetic syndrome. Evaluation of complications such as altered gait and feeding disorders may require special diagnostic studies, such as gait analysis and videofluoroscopic swallowing studies. Routine screening for metabolic and genetic disorders is not recommended unless the child has atypical features, such as unusual facial features, or a progressive condition.

## INTERVENTION

Pathophysiologic abnormalities of the brain (eg, leukomalacia) lead to impairments such as spasticity. Spasticity then leads to alterations in functioning (eg, shortened stride length), which leads to disabilities (eg, difficulty ambulating independently). The functional impairments associated with CP may affect independence, emotional and social well-being, community participation, and life satisfaction. Adults with CP have identified communication skills, self-care activities, and mobility as the 3 most important issues they face. Consequently, interventions (eg, medications, surgery, braces or adaptive equipment) should focus on promoting developmental and functional outcomes that address these issues rather than on simply reducing spasticity, improving range of motion, or correcting deformity in isolation. No intervention, including therapy and surgery, will be worthwhile in

the long term if it does not improve the child's ability to function. Interventions should also stress the prevention of complications.

Table 226-1 lists referrals and interventions that might improve outcomes for children with CP. No single professional can address the multifaceted medical, social, psychological, educational, and therapeutic needs of a child with CP. Comprehensive management requires an interdisciplinary team of physicians who guide interventions designed to maximize the development and function of each child. IDEA mandates access to early intervention services for infants at risk for disabling conditions. These services include special education; physical, occupational, and speech therapies; adaptive equipment; training for mobility and living skills; and communication. The therapies may not change the basic disorder significantly; however, the interventions guide parents in how to position and handle their infant, provide options for play and learning activities, and facilitate feeding and the parent-child relationship. In addition to therapies, early intervention providers can offer anticipatory guidance and family support as they adjust to the responsibilities of raising a child with CP.

The care provided should be integrated. For example, children whose legs are spastic often have dorsiflexion at the ankle, flexion at the knee, and flexion and adduction at the hip. Multiple interventions are possible, including muscle strengthening, orthotics (eg, ankle-foot orthoses), oral medications, botulinum toxin injections (with or without serial casting), intrathecal baclofen therapy, selective dorsal rhizotomy, and orthopedic surgeries. Deciding on the best approach requires the input of the child and family in collaboration with a team of physicians, including therapists, orthotists, nurses, physicians, and social workers. Even with a single intervention (eg, orthopedic surgery), multiple options are available. For instance, orthopedic repair of only 1 or 2 of these problems may leave the child unimproved or worse, and therefore all 3 problems should be addressed. Gait analysis using videography, electromyogram, and sensors has improved the orthopedic care given to these children. After orthopedic surgery, therapy should be started to maximize range of motion, strength, and function.

Oral medications (eg, diazepam, baclofen, tizanidine, dantrolene) can be used to reduce spasticity, but these drugs may have adverse effects, and evidence for their functional benefits is limited. Selective dorsal rhizotomy and intrathecal baclofen are neurosurgical interventions that reduce spasticity and increase range of motion. Intramuscular botulinum toxin, toxin type A, is effective in children who have functional spasticity in transiently reducing spasticity in individual limbs. Although these treatments can reduce spasticity, they cannot improve selective motor control, difficulties with balance, and weakness. Strength training has shown promise in improving function. Various casting and splinting techniques that may maintain muscle length and inhibit increased tone may be helpful. In many cases, orthopedic procedures such as tenotomies, tendon releases, and transfers are necessary to address soft tissue and bone problems. Information regarding the

effect of surgery on function is limited. Constraint therapy (ie, immobilizing the dominant upper extremity) while providing therapy to enhance the function of the affected limb has been shown in several studies to improve function in children who have spastic hemiplegia. Evidence suggests that constraint therapy produces anatomic changes in the brain on functional MRI.

Drooling is often a significant social problem for children with CP and may be managed with scopolamine, which is available as a transdermal patch and as a tablet; glycopyrrolate; botulinum toxin injections into salivary glands; or surgical removal of the salivary glands. Because children who have CP are at increased risk for nutrition and feeding problems, careful monitoring of their physical growth is critical. Both linear growth and weight may be affected; therefore, monitoring weight for length rather than weight alone is important. Reliable measures of height or length in children who have CP are often impossible to obtain because of the scoliosis, fixed joint contractures, involuntary muscle spasms, and poor cooperation stemming from cognitive deficits. Tibial length has been used as a proxy for height. Evaluating the child whose growth is impaired includes evaluation of dietary intake for calories and content and evaluation for gastroesophageal reflux (using impedance probe, endoscopy with biopsy, or radionuclide gastric emptying study). A clinical feeding evaluation includes assessing the child's seating and posture during meals, as well as assessing the swallowing mechanism, which can be aided by a videofluoroscopic swallowing study using foods of different consistencies. The videofluoroscopic swallowing study can also assess the risk for aspiration. The assistance of feeding specialists is invaluable in this evaluation. Treatment options may include providing special seating devices to maintain the child in an upright, neutral position; thickening feedings; or inserting a gastrostomy tube with or without fundoplication. Enteral nutrition generally promotes weight gain and overall health, but may not restore longitudinal growth. As children who rely on caregivers for total assistance grow, their increasing body size can pose barriers for family and community participation. In these instances, parents may consider growth attenuation; however, physicians are encouraged to consult with endocrinologists and ethicists because there has been significant public debate surrounding this approach to care.

Pediatricians and primary care physicians should advocate for each child with CP in their care. In addition to the individual needs of children and their families, physicians are encouraged to advocate for educational and other community services that promote participation of persons of all abilities. Primary care physicians cannot be expected to understand all the nuances of the interventions used in the treatment of their patients with CP (Which braces are best? Should the child be treated with botulinum or baclofen?), but they can be active participants in the overall care of the child by monitoring the child's function (nutrition, mobility, activities of daily living, communication, and ensuring participation at the maximal level).

Because many conventional therapies do not adequately address the secondary conditions of CP,

families often turn to complementary therapies. The pediatrician should inquire about the use of these treatments and be aware of their nature, possible interactions with medications, and potential for harm. Complementary, integrative, and alternative treatments, such as equine-assisted therapy (hippotherapy) and acupuncture, have been shown to offer functional benefits to some children with CP. There is no evidence to support the use of hyperbaric oxygen to promote the motor function of children with CP, which also is associated with risks for increased seizures and barotrauma to tympanic membranes. Similarly, patterning and various forms of electrical stimulation have undergone trial, but evidence for their effectiveness is lacking.

## PROGNOSIS

Survival in children who have CP depends on the severity of the condition. For example, a 2-year-old with severe CP would be expected to have a 40% chance of living to age 20 years, whereas a child with mild CP would have a 99% chance. Respiratory diseases (eg, pneumonia), epilepsy, and congenital malformation are the most commonly recorded causes of death in childhood. Life expectancies among adolescents and adults with CP are lower for those with more severe limitations in motor function and feeding skills, although over the past 3 decades, significant improvements in survival are noted overall.

Children who have intellectual disability, no independent mobility (ie, rolling), or limited spontaneous movement and can be fed only by gastrostomy tube are at the greatest risk for early death. Prognostication before the child's second birthday may be difficult, except at the extremes of involvement. In general, the prognosis for functioning is related to the clinical type of CP, pace of motor development, evolution of infantile reflexes, intellectual abilities, sensory impairment, and emotional-social adjustment. Patients who sit unsupported by 24 months of age and crawl by 30 months of age are more likely to eventually walk independently. Most children who first sit between 3 and 4 years of age walk only with aids or braces or have restricted functional ambulation. Retention of obligatory primitive reflexes at 18 months of age makes independent ambulation unlikely. Virtually all children who have hemiplegia learn to walk, as do many who have dyskinesia or ataxia. Children who walk before 2 years of age are more likely to have a normal or borderline IQ. Individual achievement is related to many factors, such as intelligence, physical functioning, ability to communicate, and personality attributes. The availability of accessible primary and specialty health care, strong educational and vocational programs, supportive family involvement, and opportunities for community participation contributes to adult functional outcomes.

Long-term planning and preparation are required to help children with CP make the transition from adolescence to adulthood, particularly when a child has multiple needs. A variety of assistive technologies, such as switches that improve the individual's ability to control the environment, computers, and small electric motors that may replace some motor activities,

are available. Speech synthesizers, symbol charts, or spelling boards can enhance an individual's ability to communicate effectively. Simple environmental enhancements, such as ramps or accessible showers, and assistive devices, such as a pencil holder or mouth-activated switch, can improve the quality of life dramatically for individuals with CP. IDEA requires that school-aged children who have disabilities be assessed for the utility of assistive devices and be given the support needed to use them effectively. Gaining access to these services requires coordination of care, knowledge of the resources available in the community, referral to experts, and financial assets. The physicians who care for children with CP are encouraged to ensure that these services are available both to the patient and to the family.

The overall goal for children with CP should be to maximize functional independence and participation in family and community activities with their typically developing peers. Opportunities for participation may be limited, but physicians should be diligent in identifying these opportunities and encouraging children to participate in any and all activities that are available.

### WHEN TO REFER

- In the United States, all infants who have CP who are younger than 3 years should be referred to an early intervention program.
- All children who have moderate or severe CP should be referred to an interdisciplinary clinic, if one exists. If not, then they should be referred to an orthopedist, physical therapist, and a professional (developmental pediatrician, neurologist, pediatric rehabilitation specialist) who understands the needs of children with CP and can manage spasticity and other abnormalities of tone, and optimize functioning.
- Children who have CP and seizures should be referred to a neurologist. The primary care physician in the medical home should coordinate these referrals and ensure that the child is receiving coordinated, comprehensive care.
- Gastroenterologist or aerodigestive clinics should be consulted for children with CP who have feeding or nutritional impairments that might need the support of enteral feeding.
- When the etiology of CP is not established, or when the child is following an atypical course and showing congenital anomalies, consultation with geneticists is encouraged.

### WHEN TO ADMIT

- Some children who have CP aspirate food or saliva into their lungs; others have inadequate nutrition. Therefore, they demonstrate increased susceptibility to acute illnesses, such as pneumonia, and are likely to become more ill with these illnesses. They should be hospitalized if they are severely ill or cannot be managed at home. They should be hospitalized for most major surgeries as well, such as complex orthopedic procedures.

## Chapter 227 CHICKENPOX

David W. Kimberlin, MD; Nathan Price, MD

Chickenpox (varicella) is a childhood viral disease characterized by a pruritic vesicular rash that appears in crops. It is highly contagious and has been regarded as a relatively benign disease, in as much as complications are rare in healthy children. However, in the pre-vaccine era, more than 100 persons died every year from varicella, and the increasing number of children who are at risk for severe disease because they are immunosuppressed ensures that varicella remains a pathogen capable of causing significant mortality and morbidity. Additionally, the economic and social costs of days lost from school and from the work force by parents have driven interest in this disease and in its prevention through immunization.

The *chicken* in *chickenpox* is thought to derive from its likeness to the chickpea *Cicer arietinum*, or from the French for chickpea, *pois chiche*. Other researchers postulate that the name may come from the Old English word for itch, *gican*. The word *varicella* is derived from a disease that is similar in appearance but is much more severe, namely variola (smallpox).

### ETIOLOGY

Chickenpox is caused by the varicella-zoster virus (VZV), a DNA virus and member of the herpesvirus family. The same virus causes both chickenpox and herpes zoster, the latter being a reactivation (after a usually prolonged latent phase) of the initial varicella infection. Varicella-zoster virus can be detected in the vesicles of both chickenpox and herpes zoster, as well as in blood, tissue, and respiratory secretions during active disease. The virus is highly labile, losing its infectivity quickly in the external environment. Inactivation can also be accomplished by heat and trypsin. Only 1 serotype of VZV has been isolated, but different virus strains, including vaccine strains, can be identified by means of polymerase chain reaction (PCR).

### TRANSMISSION

Chickenpox is one of the most contagious viral infections to cause disease in humans, with an attack rate of 87% in susceptible individuals, making it only slightly less contagious than measles and smallpox. Infection is thought to be spread by respiratory secretions because airborne particles from patients can transmit infection before onset of the rash. Virus only rarely has been cultured from these secretions, although its presence can be detected by PCR. Contact with the vesicular fluid of chickenpox or herpes zoster also may result in the transmission of chickenpox infection.

Indirect contact (fomite transmission) is probably rare because of the lability of VZV, although viral DNA has been found on environmental surfaces during outbreaks. Chickenpox in a seronegative

pregnant woman can also lead to transmission of infection to her fetus or newborn. Transplacentally acquired antibody to VZV is partially protective to the newborn, but chickenpox can occur in young infants born to immune mothers. This may be more likely in mothers who did not have chickenpox disease but rather were immunized against varicella. Zoster is much less contagious than chickenpox (approximately 15% attack rate), and transmission of chickenpox from zoster is thought to occur primarily from direct exposure to the rash, although cases have been reported of virus being transmitted despite appropriate contact precautions being taken. Virus has been cultured from saliva in patients with zoster, and DNA has been found to persist in the saliva for up to 12 years. Furthermore, virus was cultured in asymptomatic, stressed astronauts, raising the question of the role of asymptomatic or persistent shedding of virus in chickenpox transmission.

### EPIDEMIOLOGIC FACTORS

Humans are the only known reservoir, or natural host, of VZV. The communicability period lasts from 1 or 2 days before the onset of the rash until 5 days after the onset or until all vesicles have crusted. Most vesicles no longer have detectable virus particles after 5 days. The incubation period is between 10 and 21 days, with an average of 14 to 16 days, although this period can be shortened in immunocompromised patients and prolonged in persons who receive immunoglobulin therapy as postexposure prophylaxis. Secondary household cases are often more severe because of increased exposure inoculum.

In temperate climates, chickenpox is mainly a disease of childhood, with 80% to 90% of children historically having been infected by 9 to 10 years of age. Historically, the highest incidence of varicella in the United States was among children aged 1 to 9 years. In the pre-vaccine era (eg, before 1995), approximately 4 million chickenpox cases occurred yearly in the United States, with 90% of cases occurring in children. The disease occurred throughout the year, but most cases occurred during the winter and spring months. Children in tropical climates have a lower rate of infection, and up to 40% to 90% enter adulthood without having had chickenpox, creating a much larger pool of susceptible persons among older age groups in the tropics than in temperate climates.

Subclinical infections with serologic conversion rarely occur. However, because varicella infects most people in temperate climates as children, most adults who report a negative or equivocal history of chickenpox are immune. Infection generally confers lifelong immunity in normal hosts, but second clinical infections can occur. Many such *second cases* may represent situations in which a prior nonvaricella exanthematous illness was erroneously labeled as chickenpox.

Case fatality rates from chickenpox fluctuated in the pre-vaccine era, but during the period of 1990 to 1994, they were estimated to be 4.7 per 100,000 infant cases, 0.8 per 100,000 cases for 1- to 4-year-olds, 1 per 100,000 cases for 5- to 9-year-olds, 1.6 per 100,000 cases for 10- to 14-year-olds, 5.9 per 100,000 cases for 15- to 19-year-olds, and 21.3 per 100,000 cases for affected individuals

older than 20 years. The case fatality rates are higher for neonates, older adults, and immunocompromised patients. In the pre-vaccine era, varicella caused more than 10,000 hospitalizations annually, predominantly in children. Annual deaths from varicella ranged from approximately 40 to 150, with a shift from most (80%) deaths occurring in children in the early 1970s to most (54%) occurring in adults in the early 1990s. More than 90% of the childhood deaths occurred in children who had no risk factors for severe varicella.

The incidence of varicella in the United States has changed markedly since the recommendation for varicella immunization of all US children older than 1 year was made in 1995. By 2000, the incidence of chickenpox decreased overall by 71% to 84% in populations with varicella immunization coverage rates for 1- to 3-year-olds of 74% to 84%. The incidence decreased in every age group, with the greatest decrease (83% to 90%) seen in the 1- to 4-year-old age group. More recent data show that peak incidence has shifted from children younger than 10 years to the 10- to 14-year age group, although overall varicella incidence remains markedly lower than in the pre-vaccine era. By 2001, the varicella-related hospitalization (VRH) rate in the United States had declined by 75% overall, with fewer than 3,800 such hospitalizations by 2001. This reduction in VRH was seen in all age groups but was greatest for young children, such that adults accounted for nearly one-half of VRHs by 2001, compared with only one-third of VRHs in the pre-vaccine period. In a similar fashion, deaths in the United States caused by varicella in the vaccine era have dropped by 88% overall, with a 97% decline in mortality of children and adolescents younger than 20 years. It is interesting to note that in 2008, the only 2 deaths caused by varicella reported to the Centers for Disease Control and Prevention (CDC) occurred in unimmunized adults born outside the United States.

### PATHOGENESIS

Varicella virus gains entry into the susceptible individual through the respiratory tract or conjunctiva through droplet or airborne transmission. It migrates to the regional lymph nodes, where primary replication occurs. Approximately 4 to 6 days later, a primary viremia spreads the virus to internal organs, where secondary replication occurs. This event is followed by a secondary viremia, which spreads the organism to the skin and is followed by clinical chickenpox. Viremia has been documented in blood-borne monocytes 9 to 12 days after exposure but 1 to 5 days before onset of the rash. The appearance of the rash in crops may be the result of an intermittent secondary viremia.

The rash is, at first, macular and then progresses to a papular lesion that contains a minute vacuole. Fluid accumulates in the vacuole, causing a vesicle to appear on a reddened base to produce the classic *dew-drop on a rose petal* lesion. Multinucleated giant cells and intranuclear inclusions can be identified microscopically in the base and on the edges of the vesicle. As the rash resolves, the vesicle becomes cloudy and fills with fibrinous fluid and leukocytes. A crust develops that may remain attached for 1 to 2 weeks. As the rash progresses, all stages (papule, vesicle, crust) are

present simultaneously, distinguishing it from smallpox, in which all lesions are in the same stage of progression. When a vesicle occurs on mucous membranes, its roof sloughs to leave a shallow ulcer. Evidence suggests that interferon, produced by the polymorphonuclear cells in the lesion, may contribute to resolution of the disease.

## CLINICAL MANIFESTATIONS

### Healthy Children

Chickenpox begins with a mild febrile prodrome in 36% of unvaccinated and 25% of vaccinated children. Prodromal symptoms usually are more noticeable in adults but can occasionally be severe in children as well. A complaint of malaise, vomiting, upper respiratory infection, or other prodromal symptoms can be present in up to 45% of unvaccinated children. This phase is followed in a few hours to days by a macular rash, usually beginning on the scalp, neck, or upper portion of the trunk. The macules progress to a papular, vesicular, pruritic rash, usually within 12 to 24 hours. Vesicles appear in crops, with a new crop occurring every 1 to 2 days over the next 2 to 5 days, resulting in multiple crops during the illness. Typical childhood cases produce a total of 250 to 500 lesions. The vesicles turn to pustules and then crust over. The illness usually runs its course in 5 to 10 days. At the height of the disease, lesions in all phases from early vesicles to crusts can be seen. Fever varies from none to 102°F (38.9°C) at the onset of the disease and may continue until vesicles cease to appear. The rash spreads centrifugally and involves all areas of the skin in severe cases. Vesicles are pruritic, and exco-riations frequently are seen. Lesions occur more frequently in areas of irritation or dermatitis or in skin folds. Occasionally, the rash appears as a macular rash in the diaper area or on the trunk and remains for 1 or 2 days before becoming vesicular, making early diagnosis more difficult. Vesicles may occur on the mucous membranes of the mouth, conjunctiva, esophagus, trachea, rectum, or vagina. Generally, little scarring occurs, unless the lesions become superinfected or are continually traumatized. Areas where chickenpox lesions have occurred, however, may remain hypopigmented or hyperpigmented months after the rash has resolved. Occasionally, lesions are bullous as a variant of the disease itself, but these are more often caused by staphylococcal superinfection. White blood cell counts and other laboratory test results are usually normal in uncomplicated varicella.

### Older Children and Adults

Chickenpox in older children and adults usually is more severe than it is in younger age groups, with a prodrome that may include irritability, listlessness, headaches, chills, anorexia, and myalgia. Fever is usually present and is higher and more prolonged than it is in the young child. The rash also tends to be more severe, and the risk for complications is greater.

### Breakthrough Chickenpox in Previously Immunized Children

Breakthrough disease is defined as wild-type chickenpox that occurs 42 days or later after vaccination. Risk

factors for breakthrough disease include immunization before 15 months of age, low 6-week postvaccination varicella zoster antibody titers, longer elapsed time since immunization, oral steroid use, and receipt of measles-mumps-rubella vaccine (MMR) within 28 days before varicella vaccine. In most children, breakthrough disease typically produces milder systemic symptoms and fewer lesions (usually <50) that are less pruritic and crust over faster. In some cases, the lesions may appear only as papules that never vesiculate, making diagnosis difficult. In addition, children with typical, mild breakthrough varicella are also approximately one-half as likely to transmit the disease to household contacts.

### Immunocompromised Children

Immunocompromised children usually have the most severe symptoms; they, along with neonates, are at greatest risk for death from chickenpox infection. *Progressive varicella* can be seen in children who have an immunocompromising condition or who are being treated with immunosuppressive therapy for leukemia or another malignancy. After a more severe prodrome, up to 30% of such immunocompromised children develop progressive varicella, with spread of VZV to the lungs, liver, pancreas, or central nervous system. Vesicles may be larger and hemorrhagic. All complications of chickenpox are increased in this population, with varicella pneumonia the most common cause of death. Even if progressive varicella does not develop, these patients still have higher fevers and more prolonged vesicular eruption than do nonimmunocompromised children.

Although severe varicella can occur in children who are infected with human immunodeficiency virus (HIV), especially those who have very low CD4 percentages, most children infected with HIV, including those who have low CD4 percentages, do not develop severe acute varicella. Many experts use oral valacyclovir or high-dose oral acyclovir to manage selected children infected with HIV who have relatively normal CD4 values, whereas others still manage *all* children infected with HIV with parenteral acyclovir (see Treatment).

Children who receive systemic steroid therapy for diseases other than cancer also are at risk for more severe involvement and complications. Children who receive 2 mg/kg or 20 mg prednisone (or equivalent) or more for 2 weeks or longer should be considered at increased risk for severe varicella. Inhaled corticosteroids do not seem to increase risk for severe varicella, but definitive data are lacking; some experts would still consider antiviral therapy in this group.

### Congenital and Neonatal Varicella

In cases of primary maternal varicella during pregnancy, VZV can cross the placenta, leading to congenital varicella syndrome in 2% of cases when maternal infection occurs during the first 20 weeks of gestation. Although congenital varicella syndrome does not usually occur late in pregnancy, there have been a few cases reported occurring after 20 weeks' gestation, the latest at 28 weeks' gestation. Cicatricial skin lesions or skin loss in a dermatomal distribution

(76%), neurologic defects (60%), eye diseases (51%), and skeletal anomalies (49%) occur in affected infants. Such infants have a mortality risk of 30%.

Maternal infection during the late third trimester of pregnancy may result in transplacentally acquired varicella in the newborn. When mothers have clinical chickenpox in the 2 weeks before delivery, 24% of their infants will develop neonatal varicella. If the onset of maternal rash occurs more than 5 days before delivery, or if rash initially erupts in infants younger than 4 days, then risk for death seems to be small. This reprieve is probably attributable, at least in part, to maternally transferred immunity. If, on the other hand, the *maternal* rash emerges between 5 days before and 2 days after delivery, or if the *newborn* rash begins at 5 to 10 days of age, then an associated 20% to 30% neonatal mortality occurs. The risk is uncertain for infants who are nursing when the mother contracts chickenpox.

Herpes zoster in pregnant women, on the other hand, seems to confer minimal risk for infection to the fetus. In a series of 366 women who had herpes zoster in pregnancy, none of the infants had evidence of intrauterine infection.

### Zoster

Zoster, or shingles, is the reactivation of VZV that has remained dormant after clinical chickenpox. The virus resides in the dorsal nerve ganglia and is reactivated by periods of decreased host immunity or other unknown stimuli. During reactivation, the rash covers the dermatome that corresponds to the infected nerve root. Disseminated zoster, however, also can occur, involving multiple dermatomes. Zoster has been described in all age groups, including in infancy after prenatal exposure to varicella virus resulting from maternal chickenpox.

Children who have varicella infections at younger ages, especially when the infection occurs before the child is 1 year of age, have an increased incidence of zoster later in life. Children with leukemia who experience varicella develop zoster at an increased incidence of 25 cases per 1,000 person-years, a significantly lower rate than that for children infected with HIV. Twenty-seven percent of children infected with HIV (before anti-HIV drugs were available) who had primary varicella after 1 year of age developed zoster 2 years (on average) after primary varicella; among children whose CD4 percentage was less than 15% at the time of varicella infection, 70% developed zoster in the same time period. The varicella vaccine seems to be quite effective in preventing zoster in children with HIV.

## COMPLICATIONS

### Secondary Bacterial Infection

Secondary bacterial infection is the most common complication of chickenpox. Children younger than 5 years seem to be at increased risk. Symptoms of secondary bacterial infection begin, on average, 4 days after the appearance of the varicella rash, often with a secondary fever. Infections are usually caused by group A streptococci or *Staphylococcus aureus*, but

serious invasive infections such as necrotizing fasciitis can be polymicrobial and often include gram-negative and anaerobic organisms. Bacterial complications include impetigo, cellulitis, abscess, necrotizing fasciitis, myositis, gangrene, arthritis, osteomyelitis, pneumonia, empyema, conjunctivitis, toxic shock syndrome (usually streptococcal), sepsis, and erysipelas. Bullous lesions caused by *S aureus* may begin on the second or third day of the rash and present as bullous impetigo.

### Neurologic Complications

Nervous system complications are the second most common complication of varicella and include acute cerebellar ataxia, encephalitis, seizures, aseptic meningitis, myelitis, and peripheral neuropathy. Many of the seizures occurring with chickenpox may just be febrile seizures; in one series, 12 of 23 patients who had varicella and seizures had concomitant fever. In older series, the mortality from neurologic complications reached approximately 10% overall, but most of the deaths occurred among cases of encephalitis, some of which may have represented unrecognized Reye syndrome.

Acute cerebellar ataxia (ACA) is the most common neurologic complication of varicella, occurring in 1 in 4,000 cases of chickenpox. The average age of patients with ACA is 4 years, with most cases occurring among children younger than 5 years. The onset of symptoms usually occurs 1 to 2 weeks after onset of varicella but ranges from 2 to 21 days after the appearance of the rash and, uncommonly, may even precede the rash. The usual clinical features of varicella-related ACA are acute onset of vomiting and ataxic gait disturbance without major disturbance in mental status. Dysmetria (68%) and trunk ataxia (74%) also occur frequently; fever and nystagmus are much less common (5% to 10%). Laboratory studies usually reveal a normal peripheral white blood cell count, normal to mildly elevated cerebrospinal fluid protein, and, in 50% of patients, cerebrospinal fluid pleocytosis. Between 95% and 100% of normal children who have varicella-related ACA recover completely with only supportive care. Most cases are mild enough that hospitalization is not necessary. Recovery usually takes place within the first 3 months, although it may take longer for some children.

### Varicella Pneumonia

Varicella pneumonia occurs most often among adults, adolescents, and immunocompromised children. It is one of the more common causes of death resulting from varicella. In children, varicella pneumonia occurs in fewer than 1 per 10,000 cases of chickenpox. In adults, the rate is higher, at 3.1 per 10,000 cases of chickenpox. Manifestations range from abnormal chest radiograph findings alone to cough, rales, tachypnea, hemoptysis, chest pain, cyanosis, and respiratory failure. Onset of pneumonia typically occurs 5 to 6 days after onset of rash in immunodeficient children and adults but occurs within the first 3 days of rash onset in immunocompetent hosts (adults). Chest radiographs typically show diffuse, reticulonodular densities of various sizes, which are best viewed in the lung periphery. As the disease progresses, nodules may enlarge and coalesce into extensive infiltrates.

Treatment of varicella pneumonia with intravenous acyclovir is recommended; however, mortality is still 10% to 20%, reaching higher rates among severely immunodeficient patients.

### Hematologic Complications

Thrombocytopenia is the most common hematologic abnormality seen with varicella. Thrombocytopenia may occur with an invasive secondary bacterial infection or sepsis, in which case it is associated with more severe illness and worse outcome. In the absence of secondary bacterial infections, however, varicella may produce thrombocytopenia (or even pancytopenia) that is attributed to infection-related suppression or antibody-mediated destruction (immune thrombocytopenic purpura) of platelets. Onset occurs 3 days to 3 weeks after the chickenpox rash appears. Febrile purpura, malignant chickenpox with purpura, postinfectious purpura, purpura fulminans, and Henoch-Schönlein purpura have all been described in association with varicella infection.

### Hepatitis

Hepatitis has been reported during chickenpox infections and is marked by the onset of abdominal pain, vomiting, and continued fever on the second to fourth day after the rash appears. Liver function tests become abnormal but return to normal with resolution of the abdominal symptoms. No progression to classic Reye syndrome occurs, and the blood ammonia level is normal. However, some experts think that some of these cases may represent low-grade Reye syndrome. One study of 39 children who had uncomplicated chickenpox found 47% to have a mildly increased level of aspartate transaminase (serum glutamic-oxaloacetic transaminase) and 29% to have significantly increased aspartate transaminase levels.

### Reye Syndrome

Reye syndrome is an acute illness occurring almost exclusively in children and characterized by encephalopathy and fatty degeneration of the liver. Reye syndrome carries a high case fatality rate of 30% overall, reaching rates of 43% for children younger than 5 years. In 1980, the association between Reye syndrome and use of aspirin during varicella or influenza illnesses was first reported. This report led to an advisory from the CDC in 1980, a Surgeon General advisory in 1982, and mandatory warning labels on all aspirin-containing medications in 1986 cautioning physicians and parents to avoid using salicylates in children who have varicella or influenza-like illnesses. The annual number of reported cases of Reye syndrome in the United States fell from a high of 555 cases in 1980 to no more than 36 cases per year from 1987 to 1993 and no more than 2 cases per year from 1994 to 1997. Given its rare occurrence, any child suspected of Reye syndrome should be evaluated thoroughly for the presence of another metabolic disorder.

Salicylates should be avoided in any child who has chickenpox. Reye syndrome has not been described in relation to varicella vaccination, but it is recommended that salicylates be avoided for 6 weeks after varicella vaccination.

### Other Complications

Appendicitis, myocarditis, arthritis (viral), nephritis, orchitis, splenic hemorrhage and rupture, pancreatitis, pericarditis, and parotitis have been reported, although rarely. The most common ophthalmologic complication is papillary conjunctivitis, but keratitis, uveitis, optic neuritis, chorioretinitis, acute retinal necrosis, and progressive outer retinal necrosis also can occur.

### DIAGNOSIS

Chickenpox is usually diagnosed clinically. A history of exposure in the previous 10 to 21 days may be present. White blood cell counts are usually normal. Historically, a Tzanck test (scraping of the base of a vesicle and staining with Giemsa or Wright stain) is positive for multinucleated giant cells in VZV infections. However, herpes simplex types 1 and 2 also produce a positive Tzanck test. Varicella zoster virus-specific direct fluorescent antibody (DFA) testing of vesicle scrapings can provide specific diagnostic confirmation within hours. Scrapings of the vesicle base can also be cultured for VZV, but growth may take weeks, and overall yields are low. PCR tests have been demonstrated to be superior to viral culture in identification of varicella virus from vesicles and can be used to distinguish eruptions caused by wild-type and vaccine virus, as well as to distinguish chickenpox from monkeypox or smallpox. Viral titers during acute and convalescent stages can document a recent infection if acute titers are obtained early in the illness (preferably day 1 or 2), and higher titers are noted during convalescence 2 to 6 weeks later. Commercially available antibody tests should be interpreted with caution because they may not be sensitive enough to reliably detect vaccine-induced immunity and frequently are negative even when wild-type chickenpox was clearly present earlier in life. The only methods to reliably detect vaccine-induced antibody in serum are gpELISA and FAMA, neither of which are generally commercially available.

### DIFFERENTIAL DIAGNOSIS

Smallpox (variola) was historically the most important disease to be differentiated from chickenpox and has once again become a concern because of its use as a bioterrorism agent. The clinical prodrome of smallpox is typically more severe than that of chickenpox. Unlike varicella, in which lesions in all stages of evolution are present at once, smallpox produces an eruption in which most of the lesions are present in a uniform stage of development, progressing together from macules to papules to deep-seated vesicles and finally crusting. Involvement of palms and soles is much more typical of smallpox. Testing with VZV PCR is available through local health departments on a rapid, emergent basis when smallpox is a concern. Direct fluorescent antibody testing may also be useful to confirm varicella in cases in which smallpox is a concern.

Monkeypox is a zoonotic illness that has a prodrome and rash similar to smallpox, although usually less severe. Lymphadenopathy is prominent, unlike smallpox. Cases in the United States are rare and have been associated with animals imported from Africa.

As with smallpox, rapid testing such as VZV PCR and DFA may be useful in differentiating monkeypox from chickenpox.

Vaccinia (cowpox) produces a vesicular rash resulting from exposure to infected livestock or, when smallpox vaccine use was commonplace, from direct contact with a smallpox vaccination.

Disseminated herpes simplex can resemble the chickenpox rash, but the history and progression of the disease usually differentiate these entities. Confusion ordinarily arises only in newborns because disseminated herpes is rare; a Tzanck test will be positive in both diseases, but DFA, culture, and PCR are specific.

Rickettsialpox can resemble chickenpox, but its vesicles are deeper and are at a uniform stage of development, and prodrome is more severe.

Other viruses, especially coxsackievirus and echovirus, can produce vesicular exanthemas that usually do not crust and that follow a distinctly different course. The Tzanck test is negative in these infections. Lesions of Stevens-Johnson syndrome can resemble chickenpox, but the 2 diseases follow different clinical courses, and the rashes develop differently. A Tzanck test will be negative. Contact dermatitis may produce a rash similar to that of chickenpox, including pruritus, but has a different distribution and evolution.

Insect bites and scabies occasionally cause confusion if they are vesicular. Bullous impetigo (especially staphylococcal skin infection) may produce bullae that resemble chickenpox.

## TREATMENT

Treatment with acetaminophen for control of fever and relief of prodromal symptoms, along with measures to control pruritus, usually is sufficient. Concern has surfaced that use of nonsteroidal anti-inflammatory drugs during varicella infection may increase the risk for necrotizing fasciitis and other secondary bacterial (streptococcal) infections, but an association has not been firmly established, and its causal relationship may be confounded by the use of ibuprofen for the signs (eg, secondary fever) of incipient bacterial complications. Pruritus can be controlled with an oral antihistamine (eg, diphenhydramine), calamine lotion, Cetaphil lotion, or 0.25% menthol lotion. Uncommon but reported encephalopathic side effects of diphenhydramine may mimic neurologic complications of varicella.

Patients should be encouraged to take daily baths to help prevent bacterial superinfection. Adding baking soda or oatmeal preparations (Aveeno) to a warm bath helps relieve the pruritus. Children's nails should be kept clean and trimmed to help discourage scratching. Occasionally, gloves or socks on the hands are required to prevent opening of lesions by scratching. If superinfection is present, then it usually is a result of group A streptococci or *S aureus*. Mild superinfection of a few lesions can be treated topically with mupirocin ointment; superinfection of many lesions or of lesions in difficult areas (eg, around nares or the mouth) can be treated systemically with an antibiotic that has activity against group A streptococci and *S aureus*. Choice of empirical therapy should be based

on the local antibiotic resistance profile and severity of superinfection.

Aspirin should be avoided in the management of chickenpox because of its association with Reye syndrome. Physicians caring for patients who are taking aspirin chronically for juvenile idiopathic arthritis or other diseases need to consider the risks versus the benefits of this therapy on an individual basis if such a patient contracts chickenpox.

Hospitalization should be avoided whenever possible because hospital epidemics can occur even when the strictest isolation procedures are followed. Generally, spread is by infection of staff members who were thought to be immune or by airborne spread of the virus through ventilation systems. When unavoidable, hospitalization requires strict isolation. Hospitalization on an adult ward that has no immunosuppressed patients may lessen the chances of spread in hospitals where effective strict isolation is not available. All health care workers should have immunity to varicella verified at the time of hire.

## Antiviral Therapy

Acyclovir has been shown to be effective in treating varicella infections in healthy children and adolescents. When instituted within 24 hours of the onset of rash, treatment has resulted in modest reductions in duration of illness, number of cutaneous lesions, fever, and systemic symptoms. In one study, treatment of the index case with acyclovir did not change the transmission rate to other susceptible household contacts. Use of acyclovir for varicella infection in adolescents should be considered because they are at greater risk for more severe disease; however, use of acyclovir in healthy preadolescent children is not routinely recommended. Acyclovir can also be considered for other nonimmunocompromised children who are at increased risk for more severe varicella, including children with chronic lung disease, those with chronic skin disorders, those on salicylate therapy, those taking aerosolized or low-dose systemic corticosteroids, and those who are secondary household cases. Valacyclovir, a prodrug of acyclovir, has greater oral bioavailability than oral acyclovir. Its use is approved by the US Food and Drug Administration for children 2 years of age and older with varicella. Nonimmunocompromised patients 2 years and older in whom therapy is desired on an outpatient basis may be given valacyclovir at 60 mg/kg per day in 3 divided doses (maximum, 3,000 mg/day) for 5 days. Its effectiveness has not been studied extensively in children. A recipe for compounding valacyclovir for use in younger children is available in the package insert. Alternatively, oral acyclovir at 80 mg/kg per day in 4 divided doses (maximum, 3,200 mg/day) for 5 days may be used in all age groups. Famciclovir has been licensed for treatment of zoster in adults, but it has not been adequately studied in children for the treatment of chickenpox. Healthy children who develop complications suggestive of severe or disseminated disease, such as pneumonitis, encephalitis, or other visceral involvement, should be hospitalized and treated with intravenous acyclovir.

Acyclovir, generally by the intravenous route, has been recommended for the treatment of immunocompromised children who develop varicella infection because it can prevent severe disseminated disease in this group of patients. Because dissemination usually occurs within the first few days, benefit is most likely achieved if started within the first 24 hours after the appearance of rash. However, viral replication may be prolonged beyond the typical 72 hours that is seen in immunocompetent patients, and starting acyclovir beyond that time may still ameliorate disease. Intravenous acyclovir is given at 30 mg/kg per day in 3 divided doses if younger than 1 year, and 1,500 mg/m<sup>2</sup> per day in 3 divided doses if 1 year or older (some experts would recommend 30 mg/kg per day in 3 divided doses in all age groups). Length of therapy is usually at least 7 to 10 days, but therapy should be continued until no new lesions have occurred for 48 hours. Occasionally, lesions can recur after cessation of acute therapy in immunocompromised patients. In this situation, new lesions after a short course of therapy are not likely a result of antiviral resistance. Some experts would recommend another course of acyclovir in this setting. Increasingly, children infected with HIV, particularly those who have higher CD4 percentages, have been treated successfully for primary varicella with oral valacyclovir or oral acyclovir.

Localized zoster uncommonly occurs in immunocompetent children. The risk for dissemination and severe disease is unlikely in this population and typically does not require antiviral therapy. The exception to this is zoster ophthalmicus, in which systemic and topical acyclovir therapy may be indicated to treat ocular disease and prevent severe sequelae. Valacyclovir may also have benefit in this setting, but its use for this indication has not been evaluated in children. Patients with zoster ophthalmicus should have serial ophthalmologic evaluations. In immunocompromised patients, the risk for dissemination from zoster is higher, and intravenous acyclovir therapy should be instituted, preferably within the first 72 hours of rash onset.

Acyclovir resistance is rare in varicella and most often occurs in immunocompromised patients on prolonged antiviral therapy. Foscarnet is the drug of choice for treatment of acyclovir-resistant varicella disease.

Varicella zoster immune globulin (VariZIG) and immune globulin intravenous (IGIV), although useful in postexposure prophylaxis, are not effective once disease is established and are not recommended as treatment in this situation.

## Prevention

Every attempt should be made to prevent disease in susceptible individuals. This is done by providing age-appropriate immunization before exposure, and during an outbreak by limiting exposure to persons with chickenpox. If a patient is exposed to VZV, options for post-exposure passive immunization, active immunization, and antiviral prophylaxis are outlined in Figure 227-1.

Isolation or exclusion of the child who has chickenpox to prevent exposure of individuals who are

susceptible is the easiest prevention strategy in institutional settings such as hospitals, schools, or child care facilities. This measure is not always effective, given that the disease is contagious 1 to 2 days before the appearance of the rash. Generally, isolation is not feasible for preventing household exposures.

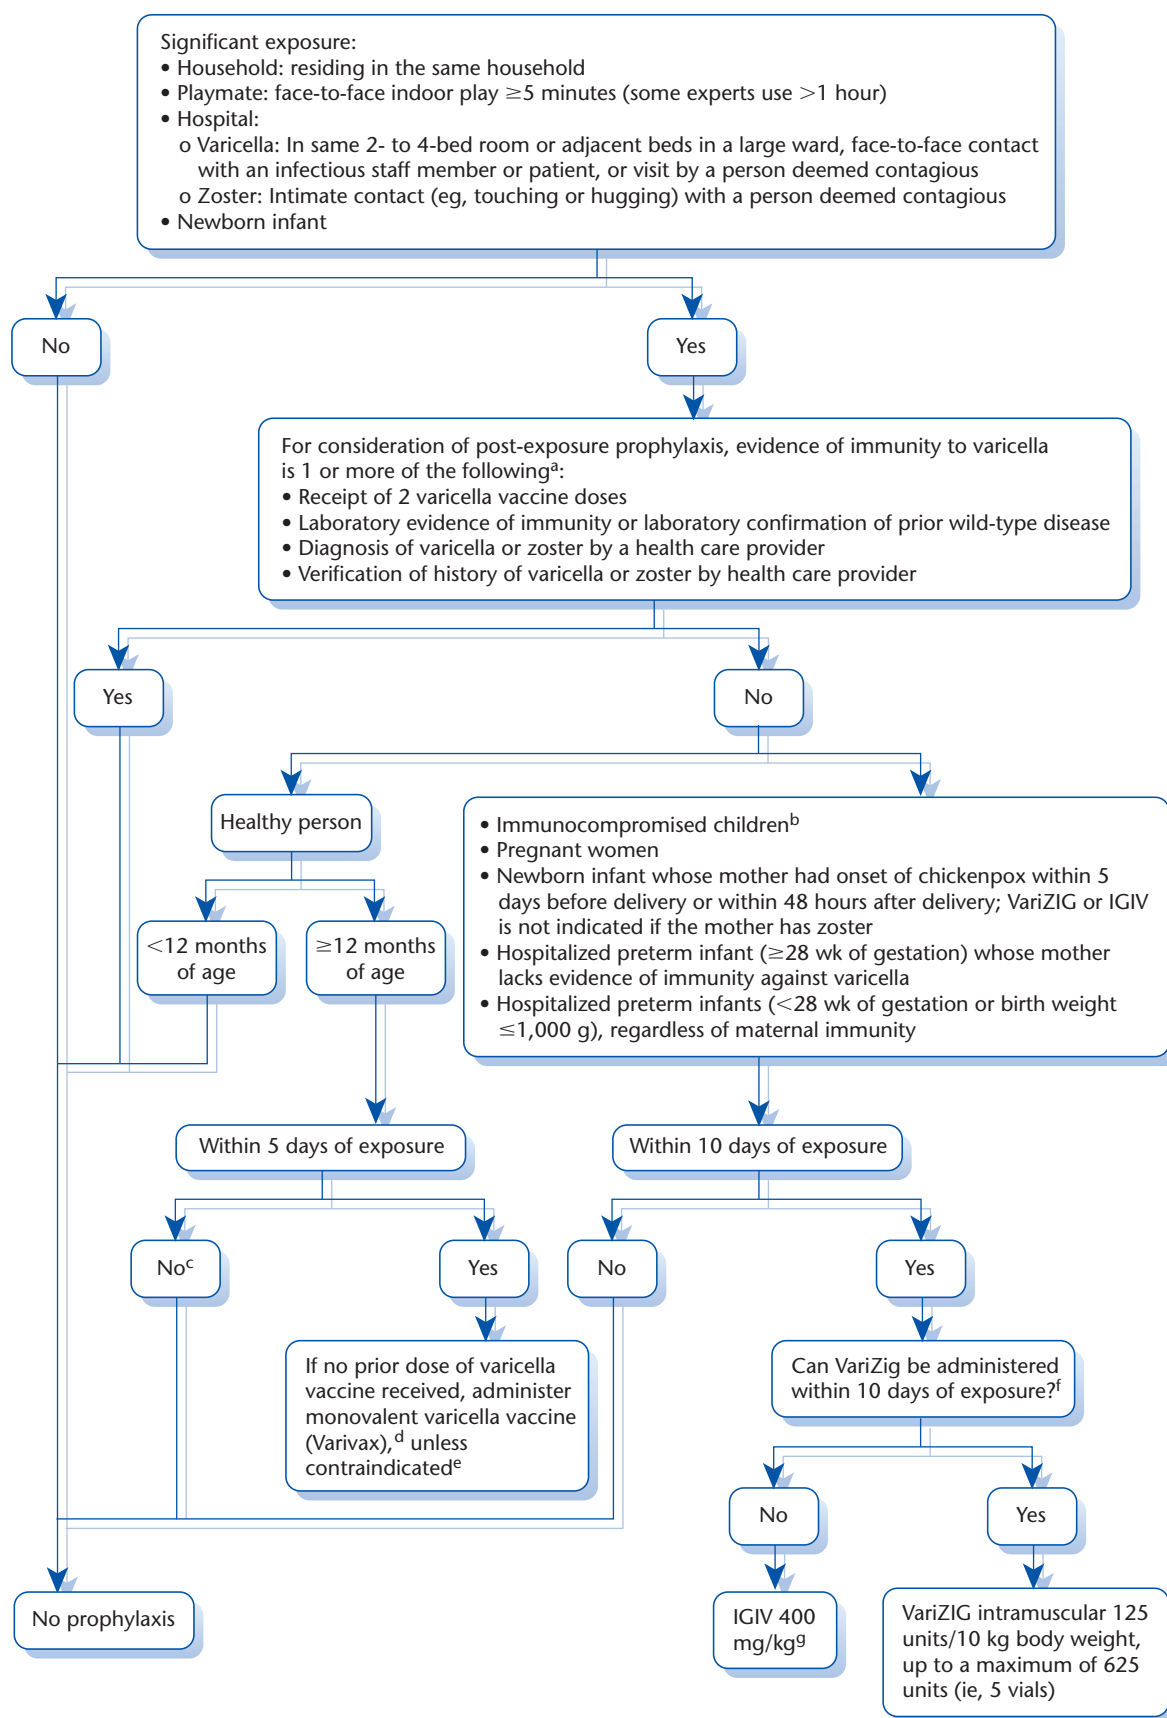

## Varicella Vaccine

A live-attenuated vaccine using the Oka strain of varicella was licensed by the US Food and Drug Administration in 1995 for the prevention of moderate to severe chickenpox in healthy persons 12 months and older. In 2005, varicella vaccine with the MMR vaccine as a combination product (MMRV) was licensed for use in healthy children aged 12 months to 12 years based on its safety and immunogenicity in children. A second varicella vaccine dose was recommended in 2006 to also protect against mild chickenpox.

Varicella vaccine has been shown to be effective in preventing varicella infection in most recipients, often attenuates infection in the case of breakthrough disease, and may decrease rates of zoster. Ten-year efficacy of a 2-dose vaccination regimen is 96% for prevention of all disease, and 100% for prevention of severe disease. This degree of protection is equivalent to immunity conferred by wild-type disease. Limited data demonstrate persistence of humoral and cell-mediated immunity following vaccination for up to 20 years in Japan, but the contribution of boosting by continued circulation of wild-type varicella to maintaining immunity is unknown.

All healthy children who lack evidence of immunity (Box 227-1) should receive 2 doses of varicella vaccine. The first vaccine dose is recommended at 1 year of age, and the second at 4 to 6 years of age. For catch-up immunization in children 12 years and younger, 2 doses should be given at least 3 months apart (if the second dose is given  $\geq 28$  days after the first dose, it does not need to be repeated). For catch-up immunization in children 13 years and older, 2 doses of varicella vaccine should be given at least 28 days apart. MMRV is not licensed for use in children 13 years or older. Data are not available regarding safety, immunogenicity, or efficacy of MMRV vaccine in HIV-infected children. MMRV vaccine should not be administered as a substitute for the single-antigen varicella vaccine when vaccinating these children. The titer of Oka VZV is higher in combination MMRV vaccine than in single-antigen varicella vaccine, a minimum of 3.99 log<sub>10</sub> PFUs compared with 1,350 PFUs (approximately 3.13 log<sub>10</sub>) in each 0.5-mL dose. The other constituents are similar to those in the single-antigen varicella vaccine.

Because the varicella vaccine is an attenuated live virus vaccine, it generally is not recommended for use in pregnant women or in immunocompromised patients. This includes children who have T-lymphocyte immunodeficiency (congenital or acquired), including patients with leukemia, lymphoma, and other malignant neoplasms affecting the bone marrow or lymphatic systems, as well as children receiving long-term immunosuppressive therapy. Children receiving high-dose systemic steroids (2 mg/kg per day or more of prednisone or its equivalent, or 20 mg/kg per day of

**Figure 227-1** Prevention for children exposed to varicella-zoster virus.

<sup>a</sup>Persons who receive bone marrow transplants should be considered nonimmune regardless of previous history of varicella disease or varicella vaccination in themselves or in their donors.

<sup>b</sup>Immunocompromised children include those with congenital or acquired T-lymphocyte immunodeficiency, including leukemia, lymphoma, and other malignant neoplasms affecting the bone marrow or lymphatic system; children receiving immunosuppressive therapy, including  $\geq 2$  mg/kg/day of systemic prednisone (or its equivalent) for  $\geq 14$  days; all children with HIV infection regardless of CD4 %; and all bone marrow transplant patients regardless of pretransplant immunity status.

<sup>c</sup>No postexposure prophylaxis, but age-appropriate vaccination still recommended for protection against subsequent exposures. If the exposure occurred during an outbreak, 2-dose vaccination is recommended for preschool-aged children under 4 years of age for outbreak control.

<sup>d</sup>If 1 prior dose of varicella vaccine has been received, a second dose should be administered at  $\geq 4$  years of age. If the exposure occurred during an outbreak, a second dose is recommended for preschool-aged children under 4 years of age for outbreak control.

<sup>e</sup>Contraindications include patients who are allergic to a vaccine component, or who are immunocompromised (see above footnote), or pregnant. Caution should be used in patients on salicylates. Vaccine may not be as effective if patient has recently received IGIV, whole blood, or plasma transfusions, and for this reason it is recommended that varicella vaccine be withheld for 3–11 months, depending on the dose, after administration of these products.

<sup>f</sup>VariZIG was approved by the United States Food and Drug Administration in December 2012. The product is manufactured by Cangene Corporation (Winnipeg, Canada) and distributed in the U.S. by FFF Enterprises (Temecula, California; 800-843-7477; [www.fffenterprises.com](http://www.fffenterprises.com)).

<sup>g</sup>If VariZIG and IGIV are not available, some experts recommend prophylaxis with oral acyclovir (20 mg/kg per dose administered four times per day, with a maximum daily dose of 3,200 mg) or oral valacyclovir (if  $>3$  months of age; 20 mg/kg per dose administered 3 times per day, with a maximum daily dose of 3,000 mg) beginning 7 to 10 days after exposure and continuing for 7 days.

### BOX 227-1 Evidence of Immunity to Varicella for Determining Need for Immunization

#### DOCUMENTATION OF AGE-APPROPRIATE IMMUNIZATION

- Preschool-aged children  $\geq 12$  months of age: 1 dose
- School-aged children, adolescents, adults: 2 doses at least 28 days apart

Postimmunization serologic testing is neither necessary nor recommended after immunization, including in health care personnel.

#### LABORATORY EVIDENCE OF IMMUNITY OR LABORATORY CONFIRMATION OF DISEASE

##### VARICELLA DIAGNOSED BY A PHYSICIAN OR VERIFICATION OF HISTORY OF DISEASE

- For people reporting or presenting with typical disease, verification can be performed by any health

care professional (eg, school or occupational clinic nurse, nurse practitioner, physician assistant, physician).

- For people reporting or presenting with atypical or mild cases, assessment by a physician or physician's designee is recommended, and 1 of the following should be sought: (a) an epidemiologic link to a typical varicella case or to a laboratory-confirmed case; or (b) evidence of laboratory confirmation, if it was performed at the time of acute disease. When such documentation is lacking, people should not be considered as having a valid history of disease because other diseases may mimic mild atypical varicella.

##### HISTORY OF HERPES ZOSTER DIAGNOSED BY A PHYSICIAN

Adapted from American Academy of Pediatrics. Varicella-zoster virus infections. In: Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. *Red Book: 2015 Report of the Committee on Infectious Diseases*. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015:857.

prednisone or its equivalent) for 14 days or more should not receive varicella vaccine. Vaccine may be administered if systemic steroids have been stopped for at least 1 month. There is no contraindication to administering varicella vaccine to patients receiving inhaled, nasal, or topical steroids. Patients with nephrotic syndrome receiving chronic, alternate-day prednisone may benefit from varicella vaccine. HIV-infected children aged 1 to 8 years should receive 2 doses of single-antigen varicella vaccine at least 3 months apart starting at 12 to 15 months of age if their CD4 percentage is at least 15%. Patients whose CD4 percentage was previously less than 15% may be immunized after stable immune reconstitution occurs as evidenced by a CD4 percentage of at least 15% for

at least 3 months while on highly active antiretroviral therapy. Older children with HIV may be immunized with 2 doses of single-antigen vaccine at least 3 months apart if they have CD4 counts greater than or equal to 200 cells/mm<sup>3</sup>, although vaccination in this age group is less well studied, and risk versus benefit of vaccination should be considered.

Vaccine may also be administered to patients with impaired humoral immunity. A patient in whom some degree of immunodeficiency is present, but in whom vaccine is not contraindicated, should receive single-antigen varicella vaccine (but not MMRV). Vaccination of a patient with leukemia in remission is controversial and should only be undertaken with expert guidance after weighing risks and benefits. Generally, live virus

vaccines should be withheld for at least 3 months after cessation of immunosuppressive chemotherapy, but other factors affecting immune reconstitution, including radiation therapy, underlying disease, and immunosuppressive therapy, must be considered. A patient whose first-degree family member has a history of congenital or hereditary immunodeficiency should not receive the vaccine unless the immune competence of the potential vaccine recipient is verified.

Vaccination is also contraindicated if a patient has had an anaphylactic reaction to any component of the vaccine. Caution should be used in patients with severe acute illness or thrombocytopenia. Because of the theoretical risk for Reye syndrome, the vaccine manufacturer recommends avoiding the use of salicylates for 6 weeks after receiving the varicella vaccine.

The adverse event attributed most commonly to varicella vaccine is pain and swelling at the injection site. A mild (2 to 5 lesions on average) maculopapular or varicelliform rash at the injection site may occur in 1% to 3% of vaccine recipients, and an additional 3% to 5% of vaccine recipients may develop a more generalized varicella rash in the month following varicella vaccination. When tested by PCR, however, most rashes occurring within 2 weeks of varicella immunization are determined to be a result of infection with wild-type virus rather than vaccine strain virus. Other, more serious but much less common adverse events—encephalitis, ataxia, erythema multiforme, pneumonia, thrombocytopenia, seizures, herpes zoster—occur at lower frequencies than would be expected following natural infection.

Febrile seizures may occur after varicella vaccine, and postmarketing studies showed a seizure risk of 3 to 4 additional febrile seizures per 10,000 first-dose vaccine recipients. First-dose MMRV has a slightly higher risk of 7 to 9 febrile seizures per 10,000 vaccine recipients between 12 and 47 months of age. It is important to note that febrile seizures do not predispose to epilepsy, neurodevelopmental delays, or other long-term health impairment. Because of the slightly increased risk for febrile seizures with first-dose MMRV use, a personal or family history of seizures is a precaution for first-dose MMRV vaccination between 12 and 47 months of age. These patients should be immunized separately with MMRV and single-antigen varicella vaccines. The increased risk for seizures is not seen with second-dose MMRV vaccination, and a personal or family history of seizures is not a precaution in this situation.

Transmission of vaccine virus to susceptible contacts has been extremely rare and has occurred only in the presence of a vaccine-associated rash; therefore, vaccinees who develop a rash should avoid direct contact with susceptible, immunocompromised individuals until the rash has resolved. Presence of an immunocompromised or pregnant contact does not preclude vaccination of an otherwise eligible child. Because the rash that occurs in relation to varicella vaccine is rare and transmission is extremely unlikely, postexposure prophylaxis with VariZIG is not recommended in immunocompromised individuals exposed to a vaccine-related rash.

Because immune globulin or other blood products (except washed red blood cells) may interfere with the

immune response to varicella vaccination, vaccine should be deferred for 3 to 11 months after receipt of blood products, depending on the dose and type of blood product use. VariZIG recipients should wait 5 months before vaccination if vaccine is not contraindicated (Table 227-1). If possible, immune globulin preparations should be avoided for 2 weeks after administration of varicella vaccine. If such products must be given, the patient should at the appropriate interval either be revaccinated or tested for evidence of immunity and revaccinated if seronegative. Measles-mumps-rubella vaccine and varicella vaccine should not be given fewer than 28 days apart, but they may be given simultaneously, including as the combination product MMRV, without reducing efficacy. Antiviral medications with activity against herpes viruses can affect vaccine efficacy. It is recommended when possible that such antivirals be discontinued at least 24 hours before immunization until at least 21 days after immunization with varicella vaccine.

MMRV can temporarily suppress tuberculin skin test (TST) reactivity. Although the effect of varicella vaccine on TST reactivity is unknown, it is recommended that TST be delayed if possible by 4 weeks after vaccine administration. The same approach is suggested with respect to the interferon- $\gamma$  release assays (IGRA) as well. However, a TST may be placed, or an IGRA may be obtained simultaneously with varicella vaccine or MMRV administration.

### Postexposure Prophylaxis

The decision to use postexposure prophylaxis is based on several factors. The type of exposure, possible immunity of the exposed individual, risk for disease severity, and possible risk and benefit of the intervention must all be considered. Face-to-face contact carries a high risk for disease transmission, especially among household contacts. Experts disagree about what length of time of exposure constitutes a significant risk for disease transmission. As little as a 5 minutes could be significant, although some would argue that more than 1 hour is necessary. Sharing a hospital room with an infectious person is also deemed to be high risk. Transient interaction with infected staff at hospitals carries less risk, although infection is not impossible. Localized zoster is much less infectious, and risk for transmission is low unless the patient has close contact (touching or hugging) with someone with localized zoster.

In healthy, nonpregnant individuals 12 months of age or older who lack evidence of varicella immunity, vaccination is recommended as postexposure prophylaxis because it may prevent or attenuate disease when given within 3 to 5 days after varicella exposure (Figure 227-1). Few data exist with regard to postexposure prophylaxis benefit of administering a second dose of vaccine to single-dose vaccine recipients exposed to varicella. Administration of an age-appropriate second dose (provided at least 3 months have elapsed since last vaccine dose) could be considered in this situation to bring the patient's immunizations up to date and to possibly provide improved postexposure prophylaxis. In an outbreak setting, a second vaccine dose is recommended for both school-aged and preschool-aged children who have only

**Table 227-1** Suggested Intervals Between Immune Globulin or Blood Product Administration and Varicella Vaccine Administration

PRODUCT	ROUTE	DOSE		
		U OR mL	mg IGG/kg	INTERVAL, MO <sup>a</sup>
Tetanus prophylaxis (TIG)	IM	250 U	10	3
Hepatitis A prophylaxis (IG)	IM	0.02 or 0.06 mL/kg	3.3 or 10	3
Hepatitis B prophylaxis (HBIG)	IM	0.06 mL/kg	10	3
Rabies prophylaxis (RIG)	IM	20 IU/kg	22	4
Varicella prophylaxis (VariZIG)	IM	125 U/10 kg	20–40	5
Measles prophylaxis (IG)				
• Standard	IM	0.25 mL/kg	40	5
• Immunocompromised host	IM	0.50 mL/kg	80	6
RSV prophylaxis (palivizumab <sup>b</sup> )	IM	—	15 mg/kg	None
CMV immune globulin	IV	3 mL/kg	150	6
Blood transfusion				
• Washed RBCs	IV	10 mL/kg	Negligible	0

• Packed RBCs	IV	10 mL/kg	20–60	5
• Whole blood	IV	10 mL/kg	80–100	6
• Plasma or platelet products	IV	10 mL/kg	160	7
Replacement (or therapy) of immune deficiencies (IGIV)	IV	—	300–400	8
Therapy for ITP (IGIV)	IV	—	400	8
Therapy for ITP	IV	—	1,000	10
Therapy for ITP or Kawasaki disease (IGIV)	IV	—	1,600–2,000	11

CMV, cytomegalovirus; HBIG, hepatitis B immune globulin; IG, immune globulin; IgG, immunoglobulin G; IGIV, immune globulin intravenous; IM, intramuscular; ITP, immune (formerly idiopathic) thrombocytopenia purpura; IV, intravenous; RBCs, red blood cells; RIG, rabies immune globulin; RSV, respiratory syncytial virus; TIG, tetanus immune globulin; VariZIG, varicella-zoster immune globulin.

<sup>a</sup>These intervals should provide sufficient time for decreases in passive antibodies in all children to allow for an adequate response to varicella vaccine. Physicians should not assume that children are protected fully against varicella during these intervals. Additional doses of IG or varicella vaccine may be indicated after exposure to vaccine (see text).

<sup>b</sup>Monoclonal antibodies, such as palivizumab, do not interfere with the immune response to vaccines.

received a prior single vaccine dose, provided at least 3 months have elapsed since last vaccine dose. If more than 5 days have passed since exposure in healthy, susceptible individuals, and the patient does not develop varicella, the vaccine should be offered to prevent future varicella disease. If vaccination is contraindicated in a healthy individual, no other prophylaxis is recommended, although acyclovir or valacyclovir may be considered as postexposure prophylaxis in healthy adults that cannot receive the vaccine.

In certain high-risk individuals with whom vaccination is not possible, VariZIG, a lyophilized purified human immune globulin preparation with high anti-varicella antibody titer, should be administered after exposure to individuals with chickenpox. VariZIG has been FDA approved for use in postexposure prophylaxis. VariZIG prophylaxis is recommended ideally within 96 hours but up to 10 days after exposure in individuals without evidence of immunity and who are at risk for severe disease (Figure 227-1). Of note, stem cell transplant recipients should be considered nonimmune for postexposure prophylaxis purposes regardless of pretransplantation immunity of donor or recipient.

VariZIG is produced by Cangene Corporation (Winnipeg, Canada) and distributed by FFF Enterprises (Temecula, CA). Physicians may contact FFF

Enterprises by calling 800-843-7477, 24 hours a day to obtain VariZIG. The product can usually be delivered to the institution within 24 hours. It is available in 125-U vials, and recommended dosing is 125 U/10 kg given intramuscularly, with a minimum dose of 125 U and maximum dose of 625 U. The duration of VariZIG protection is unknown, but it should last 3 weeks (1 half-life of immunoglobulin G). Individuals re-exposed to varicella 3 weeks or longer after administration of VariZIG should receive a repeat dose.

If VariZIG cannot be obtained, IGIV at a dose of 400 mg/kg may be used. IGIV contains anti-varicella antibodies, but the titer varies from lot to lot and is not tested routinely. Individuals receiving regular high-dose IGIV infusions ( $\geq 400$  mg/kg) are likely to be protected if the most recent dose of IGIV was within 3 weeks of exposure.

If VariZIG cannot be obtained, and IGIV is unavailable, a 7-day course of oral acyclovir at a dose of 20 mg/kg per dose administered 4 times a day, with a maximum daily dose of 3,200 mg, or oral valacyclovir (if  $>3$  months of age) at a dose of 20 mg/kg per dose administered 3 times per day with a maximum dose of 3,000 mg beginning 7 to 10 days after exposure can be used in high-risk outpatients beyond the newborn period to prevent or attenuate chickenpox; however, this use of acyclovir or valacyclovir is not approved by

the FDA; it is based on small studies, and its potential effect on the immune response has not been fully evaluated.

### Chapter 228

## CHRONIC FATIGUE SYNDROME

Leonard R. Krilov, MD

Chronic fatigue syndrome (CFS) describes an illness characterized by prolonged periods of debilitating fatigue for which no definitive cause is known. The Centers for Disease Control and Prevention (CDC) have created a working definition of CFS that includes severe fatigue of longer than 6 months' duration limiting activity to less than 50% of premorbid function in association with multiple other symptoms, including new or more intense headaches, decreased ability to focus, recurrent sore throats, sensation of tender cervical lymph nodes, low-grade temperature elevations, myalgias, arthralgias, postexertional fatigue lasting more than 24 hours, and sleep disturbances (hypersensitivity or insomnia) (see Box 228-1); however, CFS is not a well-defined clinical entity. No specific

### BOX 228-1 Centers for Disease Control and Prevention Definition of Chronic Fatigue Syndrome

The following symptoms should have persisted or recurred during 6 or more consecutive months of illness and cannot have first appeared before the fatigue:

1. The individual has had severe chronic fatigue for 6 or more consecutive months that is not caused by ongoing exertion or other medical conditions associated with fatigue (these other conditions need to be ruled out by a doctor after diagnostic tests have been conducted).
2. The fatigue significantly interferes with daily activities and work.
3. The individual concurrently has 4 or more of the following 8 symptoms:
  - A. Postexertion malaise lasting more than 24 hours
  - B. Unrefreshing sleep
  - C. Significant impairment of short-term memory or concentration
  - D. Muscle pain
  - E. Pain in the joints without swelling or redness
  - F. Headaches of a new type, pattern, or severity
  - G. Tender lymph nodes in the neck or armpit
  - H. Sore throat that is frequent or recurring

causative agent or agents and no characteristic pathophysiologic models have been identified for CFS. Debate centers on the contributions of infectious and other medical conditions and immunologic and psychological factors to the clinical manifestations of CFS. All these factors likely interact to produce CFS, albeit to differing degrees in each individual.

A recent Institute of Medicine task force developed a set of criteria and suggested a new name—systemic exertion intolerance disease—to replace CFS in an attempt to better characterize this symptom complex.

Historically, a variety of syndromes that seem similar to CFS have been described. These conditions include chronic infectious mononucleosis, total allergy syndrome, chronic candidiasis, hypoglycemia, neurasthenia, myalgic encephalomyelitis, postviral syndrome, and fibromyalgia. In 2009, a newly discovered retrovirus, xenotropic murine leukemia virus-related retrovirus (XMLV), was proposed as a possible cause of CFS, but subsequent studies failed to confirm these observations, including 2 reports using samples from the patients reported in the original studies. It is thought that the polymerase chain reaction primers in the original studies were contaminated, and XMLV has been discarded as a possible cause of CFS.

Despite the lack of association of ongoing Epstein-Barr virus infection with CFS, Katz and colleagues observed that infectious mononucleosis may be an antecedent risk factor for development of CFS in adolescents.

Cases of CFS have been reported to occur both sporadically and epidemically. Overall, the CDC estimates a prevalence rate of approximately 200 cases of CFS-like illness per 100,000 adults older than 18 years in the United States. Dobbins and colleagues extracted data regarding adolescents from 3 CDC studies of fatiguing illness and reported a prevalence of CFS-like illness of approximately 20 per 100,000.

Most reported cases of CFS have occurred in white women with a median age of 35 to 40 years and from upper socioeconomic groups, although adolescents who have the diagnosis also have been described. Minorities, the indigent, and people living in developing countries are strikingly underrepresented in reports of CFS. Whether this shortage reflects a bias in patient selection or predisposing factors for development of CFS remains to be determined.

## CLINICAL MANIFESTATIONS

The primary manifestation of CFS is severe fatigue longer than 6 months in duration in association with substantial reduction in occupational, school, social, or recreational activities. Associated symptoms frequently include sore throat, low-grade fever (oral temperatures of 37.5° to 38.6° C), painful lymph nodes, unexplained generalized weakness, myalgias or arthralgias (or both), prolonged fatigue after exercise, headaches, difficulty concentrating or memory loss, and sleep disturbances (hypersomnia or insomnia). Most patients describe a sudden onset of the syndrome with an initial mononucleosis or influenza-like illness, although, in some cases, a more gradual onset is related. Many patients also describe a history of atopy or multiple allergies, or both.

The initial history should include questions about the nature and duration of symptoms, as well as possible exposures to or contacts with ill persons or risk factors, that might suggest an alternative diagnosis. Personal and social history to assess family dynamics, prior level of functioning, response to illness, family history of psychiatric illness, and psychological or family marital problems may be helpful.

The physical examination may reveal abnormalities, including mild inflammation of the pharynx, cervical or axillary lymphadenopathy, or low-grade temperature elevation in up to 50% of cases. However, the primary goal of the physical examination is to eliminate other causes for the patient's symptoms. Significantly elevated temperatures, enlarged lymph nodes (>2 cm), weight loss of more than 10% of body mass index without dieting, or focal neurologic abnormalities should suggest an alternative diagnosis. The differential diagnoses of illnesses associated with extensive fatigue are listed in Box 228-2.

## PSYCHOLOGICAL FACTORS

Physicians and investigators have noted a relationship of CFS to depressive symptoms, frank depression, and a family history of depression. Conceptually, depression may be both part of the cause of CFS and a reaction to having CFS. Family dynamics and perception (vs confirmation) of severity of illness may contribute to the development of CFS in adolescents. School-avoidance behaviors related to expectations for high academic performance compared with the teenager's abilities have been noted frequently. In many families, overprotection and overindulgence of the child have been observed, often associated with difficulty in

### BOX 228-2 Differential Diagnosis of a Patient Who Is Chronically Fatigued

- Malignancy
- Autoimmune disease
- Localized infection (eg, occult abscess)
- Chronic or subacute infection (eg, endocarditis, tuberculosis)
- Human immunodeficiency virus infection
- Fungal disease (eg, histoplasmosis, coccidioidomycosis, blastomycosis)
- Parasitic disease (eg, toxoplasmosis)
- Chronic inflammatory disease (eg, sarcoidosis, Wegener granulomatosis)
- Endocrine disease (eg, hypothyroidism, Addison disease, diabetes)
- Neuromuscular disease (eg, myasthenia gravis, multiple sclerosis)
- Drug dependency
- Side effects of chronic medications or other toxic agents (eg, chemical solvent, heavy metal, pesticide)
- Psychiatric disorder (eg, depression)
- Sleep disorders or sleep deprivation

mother-teen separation. A recent analysis of adolescents who have CFS compared with age-matched adolescent survivors of childhood cancer and a healthy control group showed that the CFS group had higher scores on measures of somatic complaints, depression, internalizing symptoms, and feeling different from others.

The manifestations of CFS can be considered in this framework as a conversion reaction in which an infection or other stressor serves as a model for persistent symptoms that offer the individual a mechanism by which to maintain an overprotective environment or to avoid going to school (see Chapter 237, Conversion Reactions and Hysteria).

### LABORATORY DIAGNOSIS

No specific laboratory tests exist by which to diagnose CFS. As with the physical examination, the primary aim of laboratory evaluations is to eliminate other conditions that may be responsible for the patient's symptoms. A suggested battery of screening tests might include a complete blood count and differential; measurement of the erythrocyte sedimentation rate, serum electrolytes, creatinine, blood urea nitrogen, and glucose; liver enzymes and function tests; thyroid function tests; tuberculin skin test with controls; measurement of alkaline phosphatase and human immunodeficiency virus (HIV) antibody; and possibly chest radiograph. Additional tests may be indicated based on history and physical examination findings. Although potential immunologic abnormalities, including altered lymphocyte subsets, qualitative defects in natural killer cell activity, hypogammaglobulinemia or hypergammaglobulinemia, elevated titers to herpes viruses (eg, Epstein-Barr virus, human herpesvirus type 6), abnormal lymphokine levels, and decreased lymphocyte proliferation responses, have been described in patients who have CFS, they have not been observed consistently in different groups of patients. Additionally, the magnitude of immunologic abnormalities detected in patients who have CFS has been small compared with those who have classic immunodeficiencies; the degree of immune aberrations does not correlate with the severity of symptoms, and opportunistic infections do not occur in CFS.

An association between low blood pressure (postural orthostatic tachycardia syndrome [POTS]) and CFS has been suggested. The role of POTS in CFS is intriguing. Assessment of upright heart rate in CFS patients with chronic orthostatic intolerance to define POTS may be helpful in a subset of CFS patients in whom dizziness is a significant complaint. Sustained excess tachycardia without hypotension and in the presence of concurrent symptoms during testing define POTS. Whether all patients with CFS should be evaluated for POTS is currently unknown.

Although of uncertain significance, increased white matter on T2-weighted magnetic resonance imaging scans suggestive of possible infiltration of the perivascular spaces, focal demyelination, or disease of the small blood vessels of the cerebral white matter has been reported in a number of patients with CFS. Presently, routine magnetic resonance imaging is not indicated in the evaluation of a patient being evaluated for CFS.

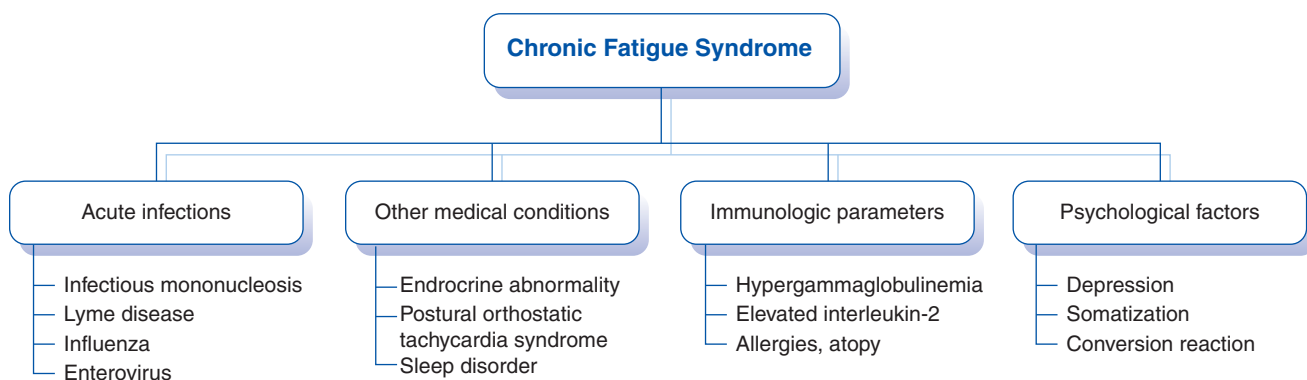

Other investigators have proposed hormonal factors, such as depressed cortisol response, as contributing to the signs and symptoms of CFS.

### PROPOSED MODEL OF PATHOGENESIS

The exact definition of a case of CFS is difficult in that few objective findings are found in these individuals, and their most severe symptoms are difficult to quantify. To date, no specific infectious cause for CFS has been defined, and a single infectious agent is not likely responsible. A reasonable suggestion would be that it is the interaction of multiple factors that results in the development of CFS (Figure 228-1). The relative importance of each of the factors probably varies from individual to individual.

### THERAPY

No specific therapy for CFS has been proved to be effective. However, management aimed at alleviating the patient's symptoms may help. If POTS is documented, then dietary (eg, increased fluid and salt intake) or pharmacologic management, or both, with drugs such as fludrocortisone, propranolol, or midodrine may be beneficial. However, treatment of POTS has been only of partial benefit in relieving CFS symptoms. Similarly, sleep studies and therapies may offer some symptomatic relief for some people with CFS.

**Figure 228-1** Pathogenesis of chronic fatigue syndrome.

An approach to the management of CFS is outlined in Box 228-3. The primary goals of this treatment are to provide counseling and symptomatic relief for depression, sleep disorders, and musculoskeletal pains; to offer emotional support with involvement of a social worker, psychologist, or psychiatrist, as needed; to identify and eliminate *secondary gain* from continuing to contribute to the illness; and to devise programs with the patient to increase school (or work) attendance and exercise capability gradually. Periodic physical examinations for possible other conditions are also important. Family therapy often helps the parents manage these issues and addresses the role of family dynamics in the evolution of a patient's symptoms. A team approach with coordination of services to avoid *doctor shopping* and fad therapy is critical to the successful management of the patient who has CFS.

Some of the unproved fad therapies described are megavitamin treatment, immune modifiers (eg, Amplegen, thymic extract, interleukin-2), magnesium sulfate, liver extract injections, anti-*Candida* diets, colonic irrigation, and removal of dental fillings. Immunoglobulin injections have been reported to be beneficial in a study of patients with CFS, although 2 subsequent studies failed to confirm this observation.

## PROGNOSIS AND FUTURE PROSPECTS

Despite the vagaries associated with the diagnosis of CFS and differences in each case, long-term follow-up suggests that most individuals report improvement or resolution of symptoms over a 2- to 3-year period. Few patients report progressive symptoms, although symptoms may wax and wane in severity. With better definition of the nature of the neurologic, cardiovascular, endocrinologic, and immunologic alterations in

CFS, additional therapeutic approaches may become available.

### WHEN TO REFER

- To resolve issues relating to possibility of ongoing infection or inflammation that may be causing the patient's symptoms.
- Given the often extensive and varied complaints of patients with CFS, multiple specialists may become involved and multiple laboratory tests may be ordered. A coordinated team approach to avoid redundant or unnecessary testing can be beneficial.
- To provide an increased level of supportive care or counseling than can be provided in the office setting, especially if the individual is not able to attend school or participate in normal activities.

## TOOLS FOR PRACTICE

### BOX 228-3 Management of Pediatric Patients Who Are Chronically Fatigued

- Confirm the diagnosis of chronic fatigue syndrome and acknowledge the symptoms as real.
- Explain and explore the potential relationship to psychological symptoms.
- Stress a coordinated approach; minimize *doctor shopping*, unnecessary testing, and unconventional therapies.
- Consider tilt-table testing or cardiologic evaluation, or both, if dizziness is a prominent complaint.
- Use stress-coping skills: modify lifestyles, decrease stress, develop a realistic schedule including working with school (gradual return to classes, home tutoring, neuropsychometric testing), and develop a graduated exercise program.
- Use cognitive-behavioral approaches: pay attention to sleep patterns and nutrition; increase activity gradually.
- Provide psychological support: provide individual therapy and family therapy; decrease secondary gain.
- Maintain follow-up: monitor physical symptoms and psychological issues; provide ongoing guidance and continued reassurance.

## Chapter 229

## CLEFT LIP AND CLEFT PALATE

Arlene A. Rozzelle, MD; Jugpal S. Arneja, MD, MBA

Clefts of the lip and palate are complicated, multifaceted problems that provide an immense challenge for treating specialists. Clefting may occur in isolation or may have several associated anomalies that represent a syndrome. As such, these problems are best addressed in a multidisciplinary team-oriented setting to maximize the child's final functional and aesthetic

**Figure 229-1** Normal palatal anatomy. (From Millard DR Jr. *Cleft Craft: The Evolution of Its Surgery*. Boston, MA: Little, Brown & Company; 1980:19.)

outcome. Aside from surgical specialists (plastic surgeons, otolaryngologists, oral and maxillofacial surgeons), cleft team members include medical specialists (pediatricians, geneticists, child psychiatrists), dental specialists (orthodontists, prosthodontists, pediatric dentists), speech and hearing specialists (speech pathologists, audiologists), and nursing specialists (pediatric or cleft-trained nurses). Results are often based on the severity of the problem, the timing of nonsurgical and surgical intervention, the experience and training of the involved specialists, and patient adherence, given that treatment is initiated at birth and is often not completed until well into late adolescence. Despite the multitude of advancements in cleft care, questions remain regarding optimizing outcomes of facial growth, dental reconstruction, speech, facial form, and psychological well-being. This chapter outlines the theoretical basics and practical approach to managing these challenging, although ultimately rewarding, patients.

## DEFINITIONS

The primary palate consists of all structures anterior to the incisive foramen (lip and alveolus), whereas the secondary palate includes all structures posterior to the incisive foramen (hard palate and soft palate). Figure 229-1 illustrates the pertinent cleft-related anatomy of the primary and secondary palate. The development of a comprehensive and completely accepted classification method for cleft anomalies has been elusive. Most classification systems are too basic, too complex, or not comprehensive enough to include all possible clinical presentations.

An early classification system divided clefts into 4 groups: (1) soft palate clefts alone, (2) clefts of both the hard and soft palate, (3) complete unilateral clefts of

the lip and palate, and (4) complete bilateral clefts of the lip and palate. In 1962, the American Association for Cleft Palate Rehabilitation proposed a complicated classification system that has not found universal acceptance. In 1971, a simple yet comprehensive diagrammatic representation of cleft classification, termed the *striped Y*, was introduced; this classification was later modified to include nasal and pharyngeal deformities. This classification system has found acceptance at numerous cleft palate centers. In 1989, a palindromic method of classifying clefts was described; the letters LAHSHAL represent the lip (L), alveolus (A), hard palate (H), and soft palate (S). In addition, a numerical recording system was proposed for the classification of clefts, termed the *RPL system*. Invariably, the method that is often used to classify and describe clefts among physicians is simply a description of the anatomic severity of the cleft of the primary or secondary palate and whether the cleft is incomplete or complete (Figure 229-2). On occasion, a complete cleft of the primary palate has a degree of skin bridging the superior aspect of the lip, termed a *Simonart band*.

## EMBRYOLOGY

Normal facial embryonic development occurs between weeks 3 and 12 of gestation with the fusion of 5 facial prominences (Figure 229-3). Specifically, palate development initiates at the end of week 5 and is completed by the end of week 12. The primary palate is derived from the fusion of the medial nasal prominences with the maxillary prominence, whereas the secondary palate is derived from the fusion of the lateral palatine processes and the nasal septum, with closure extending from the incisive foramen posteriorly. Fusion is completed by the end of week 12 with formation of the lip, alveolus, hard palate, soft palate, and uvula.

Failure of penetration or fusion of the mesenchymal masses of the 5 facial prominences forms the embryologic basis of cleft formation. Isolated failure of fusion of the medial nasal prominence with the maxillary prominence on 1 side results in a unilateral cleft lip, whereas a bilateral cleft lip results from failure of both medial nasal prominences to fuse with the maxillary prominence. Palatal clefts result from incomplete fusion of the lateral palatine processes with the nasal septum at any stage of development. As the secondary palate fuses in an anterior-to-posterior direction, soft palate clefts that occur are much more common because the fusion of the soft palate follows hard palate closure. The most accepted theory as to why secondary palatal clefts occur is delayed elevation of the palatal shelves in a vertical-to-horizontal direction.

## INCIDENCE

Clefting is the second most common congenital anomaly, after clubfoot, with an overall historical incidence of cleft lip with or without cleft palate of approximately 1 in 700 new births and an overall incidence of isolated cleft palate of approximately 1 in 1,000 new births. A 2006 study found a more accurate incidence of clefting to be 10.54 per 10,000 births, or 1 per 948. Racial differences are seen in incidence,

**Figure 229-2** Anatomic classification of cleft lip and palate. A, Incomplete cleft secondary palate. B, Complete cleft secondary palate. C, Left incomplete cleft primary palate and incomplete cleft secondary palate. D, Left complete cleft primary palate and complete cleft secondary palate. E, Bilateral complete cleft primary palate and complete cleft secondary palate.

**Figure 229-3** Embryologic development of the primary palate. LNP, lateral nasal process; MNP, medial nasal process; MXP, maxillary process; MP, mandibular process. (From Bronsky PT. Effects of hypoxia on facial prominence development in CL/fr mice. M.S. Thesis, University of North Carolina, 1985.)

with children of Asian descent having a higher incidence (2.1 in 1,000) and those of African descent having a lower incidence (0.41 in 1,000) compared with white children (1.3 in 1,000). Cleft lip and palate are more common in boys than girls (2:1); isolated cleft

palate occurs twice as often in girls as in boys, likely the result of later palatal closure in girls. Clefts are more common on the left side and theorized to be related to earlier closure of the right side, making the left side more susceptible to insult in utero. Unilateral cleft lips occur much more commonly than bilateral cleft lips (4:1). The relative frequency of orofacial clefting between cleft lip to cleft palate and cleft lip and palate is 1:1.2:2.5.

### Genetics and Risk Factors

Clefting may be in isolation or associated with other conditions that meet the criteria of a syndrome. More than 300 syndromes are associated with clefting; the more common syndromes include van der Woude syndrome, velocardiofacial syndrome, Pierre Robin sequence, Goldenhar syndrome, Treacher Collins syndrome, Down syndrome, and Stickler syndrome. Cleft lip with or without cleft palate has been suggested to be etiologically different than isolated cleft palate. Syndromes are associated with approximately 29% of orofacial clefts, with an isolated cleft of the secondary palate the most common syndromic presentation.

Most clefts are nonsyndromic and generally postulated to be multifactorial in nature or as a result of changes at a major single-gene locus. Over the past 10 years, increased study has found associations between craniofacial clefting and genetic disruptions in Sonic Hedgehog (ectodermal development), TGF- $\alpha$  (extracellular matrix protein development), TGF- $\beta_3$  (midline epithelial degradation), IRF6 (transcription), and others related to allelic association and linkage MSX1, retinoic acid receptor- $\alpha$ , homeobox genes, and B-cell leukemia or lymphoma.

Risk factors for the development of clefting include family history and environmental agent exposure. Several teratogens have been found to increase the rate of clefting during the first trimester of pregnancy. Clefting has been produced in animal models with

**Table 229-1****Familial Risks for Nonsyndromic Cleft Lip and Palate**

<b>FAMILY HISTORY</b>	<b>CLEFT LIP WITH OR WITHOUT CLEFT PALATE</b>	<b>CLEFT PALATE</b>
No family history of cleft lip or cleft palate	0.1%	0.04%
Unaffected parents with 1 previously affected child	4%	2%
Unaffected parents with 2 previously affected children	9%	1%
One affected parent	4%	6%
One affected parent and 1 previously affected child	17%	15%

exposure to several agents, including corticosteroids, ethanol, ionizing radiation, phenytoin, isotretinoin, diazepam, and methotrexate. Many of these agents have been shown to increase the risk for clefting in vivo as well; in addition, exposures to caffeine and tobacco are theorized to also increase the risk for clefting. Finally, infections, including rubella and toxoplasmosis, in the first trimester of pregnancy have also been implicated in the development of clefting. Many of these agents and exposures may act in unison in children who are biologically and genetically susceptible. A family history of clefting is a risk factor for future cleft occurrences. Table 229-1 characterizes the risk for clefting to future offspring for nonsyndromic cleft lip and palate, based on the number of parents with clefts and the number of siblings with clefts. Interestingly, although folic acid supplementation has been shown to reduce neural tube defects, there was no clear advantage to folic acid supplementation for the prevention of facial clefting until recently. Based on a recent Norwegian study, it is now suggested that folic acid supplementation of 400 mcg before conception reduces the risk for isolated cleft lip and/or cleft palate by about one-third.

### Prenatal Evaluation

Increasingly, a diagnosis of cleft lip or cleft palate can be reliably established by prenatal ultrasound, with cleft lip often easier to diagnose than cleft palate; transvaginal ultrasound can reliably detect a cleft lip by 13 to 16 weeks of gestation. Clefts of the secondary palate can be diagnosed at 19 weeks of gestation using real-time magnetic resonance imaging. Although

these techniques offer numerous advantages to the parents, in certain societies, they may result in pregnancy termination, raising important ethical concerns. Screening for other birth defects that are associated with or in isolation from clefting is now performed on a routine basis.

### MANAGEMENT

Of primary concern in the newborn with a cleft are airway stability and feeding optimization. Additionally, at this newborn time period, a general medical evaluation to rule out any associated conditions (ie, cardiac, hypocalcemia, other midline associations such as hypospadias) or syndromes is performed. Syndromic association is more likely found with an isolated cleft palate. Specifically, syndromes that are most commonly associated with facial clefting include velocardiofacial syndrome, Pierre Robin sequence, Stickler syndrome, and van der Woude syndrome. For suspicion of a syndromic association, consultation by a geneticist is recommended.

After these important issues are addressed, the remainder of the initial management plan in the first 3 to 4 months of age includes audiologic evaluation, ear-nose-throat evaluation for middle ear abnormalities, and possible orthodontic evaluation for the use of presurgical orthopedics. Surgical management follows with lip repair at 3 to 4 months and palate repair at about 1 year. Speech evaluation and therapy with or without possible surgical management of velopharyngeal insufficiency are performed in children between 2 and 4 years of age. In late childhood and during the teen years, alveolar bone grafting, lip and nose revisions, orthodontics, and orthognathic surgery follow on an as-needed basis. Care is usually coordinated through a multidisciplinary cleft team (plastic surgeon, speech therapist, audiologist, otolaryngologist, oral surgeon, dentist, orthodontist, nurse, and social worker or psychologist) following the guidelines of the American Cleft Palate-Craniofacial Association. Children with clefts are evaluated annually and, in many instances, until their management plan is completed in their late teens or early 20s. The goal of management is to achieve normal function, characterized by normal occlusion, speech, and hearing with as normal growth as possible, as well as optimal form, characterized by normal lip, nose, and facial aesthetics.

### Fetal Surgery

Much consideration has been given to repair of diagnosed cleft lips in utero, given the potential for a scarless repair and the potential for the prevention of many of the dentoalveolar and facial growth abnormalities that follow normal cleft surgery. In scarless fetal wounds, collagen is deposited in an organized, fine reticular pattern, whereas in postnatal scarring, wounds have thick and disorganized collagen matrices. However, as exciting as this procedure may sound, it is a topic of much debate, and enthusiasm should be tempered, given the intrinsic risks for premature labor and death to the mother and fetus. In addition, although an invisible scar is possible to obtain, numerous anatomic elements would remain out of position,

**Figure 229-4** Cleft feeding bottles (from left to right: Mead-Johnson nurser, Pigeon feeder, Haberman feeder, Breck feeder [syringe]).

rendering the residual lip with a potentially unnatural appearance. Currently, fetal cleft surgery is a novel concept, with no current safety and ethical standards available for clinical utility. More important than consideration of fetal surgery, if a diagnosis of cleft lip or palate is made prenatally, is appropriate consultation with specialists, including those in plastic surgery, otolaryngology, genetics, and nursing, to provide council for what is to be expected postnatally.

### Early Management Feeding

The cleft-team nurse is usually the feeding expert and will carefully monitor the nutritional status of the infant to ensure adequate caloric intake. Other feeding specialists may include occupational therapists, lactation consultants, or speech therapists. Neonates with a cleft of the primary palate (lip and alveolar ridge) can usually feed using a regular bottle or breastfeed without significant difficulty. However, infants with a cleft of the secondary palate (hard and soft palate) usually require special bottles that do not require the child to create a suction seal. These special bottles include the Haberman feeder (Medela), the Pigeon nurser (Respi-ronics), and the Mead Johnson nurser. In some cases, the infant may have to be fed with a syringe (Breck feeder) or nasogastric tube. Figure 229-4 illustrates the common cleft palate bottles used.

In addition, an infant with a cleft of the secondary palate is unlikely to be able to breastfeed because of the inability to create adequate suction. If the mother wishes to attempt breastfeeding, then a lactation expert with experience in cleft feeding should be consulted. The infant should be monitored closely by the

pediatrician, cleft-team nurse, and surgeon, with frequent weight checks. Receiving human milk is desirable for the infant, even if by bottle. To this end, supporting the mother is important, which involves a lactation consultant if necessary and providing a hospital-grade breast pump.

Many centers fit their infants with a cleft of the secondary palate with a feeding plate that is custom fabricated by the dentist or orthodontist (Figure 229-5). The feeding plate obturates the hard palate cleft, allowing infants to use their tongues to milk the nipple on the roof of the mouth and to decrease nasal regurgitation and irritation.

**Figure 229-5** Feeding plate.

### Auditory Dysfunction

Children with a cleft of the secondary palate (but not a cleft of the lip and alveolus alone) have a high incidence of middle ear disease, which is thought to be caused by eustachian tube dysfunction. This condition is caused by abnormal muscular orientation, resulting in limited drainage of the middle ear through the eustachian tube and potentially causing conductive hearing loss. These children are monitored closely for middle ear effusion and hearing impairment and are almost universally treated with myringotomy tubes to prevent chronic hearing loss and cholesteatoma, which occurred with great frequency in the past. Even a mild hearing loss of 20 decibels can result in difficulty understanding the spoken word, resulting in speech impairment. Depending on the preference of the otolaryngologist, myringotomy tubes are placed either at the time of the lip repair (about 4 months of age) or at the time of the cleft palate repair (about 9 to 12 months of age).

### Presurgical Orthopedics

Presurgical orthopedics may be passive (nasalveolar molding appliance, Figure 229-6) or active (Latham appliance, Figure 229-7). The goal of each device is to

**Figure 229-6** Nasalveolar molding appliance.

**Figure 229-7** Latham appliance.

align the alveolar segments to facilitate lip repair and improve nasal symmetry. Passive nasalveolar molding has become many centers' standard of practice whereupon the cleft of the lip is narrowed, the cleft nostril is elevated into a more normal configuration, and the alveolar ridges become aligned. Presurgical orthopedics are performed by a pediatric dentist or orthodontist, who monitors the child weekly, progressively modifying the appliance from birth to the time of lip repair as the child grows. Figure 229-8 illustrates the significant nonsurgical correction of the cleft deformity possible before the formal lip and nose repair performed at about 3 to 4 months of age.

### Cleft Lip and Palate Repair

Primary lip repair is usually performed between 3 and 4 months of age, depending on the optimization of feeding and on the results of presurgical orthopedics. The traditional metric regarding the timing of lip repair was the 10-10-10 rule: 10 weeks of age, 10 g of hemoglobin, and weight of 10 pounds. Surgical techniques for lip repair include the rotation advancement repair (Millard), the subunit repair (Fischer), and the less common triangular flap repair (Tennison-Randall). Most cleft surgeons now also perform a primary cleft rhinoplasty at the time of the lip repair, which results in enhanced nasal aesthetic outcomes. In some cases, the alveolus may also be repaired at the time of the lip repair (gingivoperiosteoplasty), providing the framework and potential for ossification of the cleft alveolar arch. Some surgeons perform a lip adhesion in the first few weeks of life, before the formal lip repair, which also molds the alveolar ridges, especially when used with a feeding plate, in preparation for the definitive lip repair several weeks later. Figure 229-9 and Figure 229-10 illustrate respective images of unilateral and bilateral cleft lip and nose repairs.

Cleft palate repair (palatoplasty) is usually performed in children between 9 and 12 months of age, although protocols vary widely at cleft centers. Repairing the palate at about 9 to 12 months of age is desirable to maximize normal speech development; however, repairing too early might result in poor maxillary growth. The 2 most common procedures to repair the soft palate are the Furlow double-opposing Z-plasty and the intraalveolar veloplasty technique of levator muscle reorientation. Various operations used to repair the hard palate include the von Langenbeck and Bardach 2-flap techniques.

### Further Management

#### Cleft Palate Speech

Even after palatoplasty, some children will exhibit velopharyngeal insufficiency or incompetence, also known as cleft palate speech, because of either muscular incoordination (as is frequently the case in velocardiofacial syndrome) or a short palate. Speech is formally assessed by a trained speech therapist in children between 18 and 24 months of age to establish a diagnosis of velopharyngeal insufficiency. A diagnosis of velopharyngeal insufficiency is often treated with speech therapy in conjunction with or without surgical management. Techniques most commonly

**Figure 229-8** A, Cleft lip and nose, pre-nasoalveolar molding. B, Cleft lip and nose, post-nasoalveolar molding.

**Figure 229-9** A, Unilateral cleft lip and nasal deformity, preoperatively. B, Unilateral cleft lip and nasal deformity, postoperatively.

**Figure 229-10** A, Bilateral cleft lip and nasal deformity, preoperatively. B, Bilateral cleft lip and nasal deformity, postoperatively.

performed include a pharyngeal flap or sphincter pharyngoplasty in children between 3 and 6 years of age. These surgical procedures partly obturate the oronasopharynx, resulting in decreased air escape through the nose, necessitating careful monitoring of the airway.

#### **Lip and Nose Revisions**

Intermediate lip and nose revisions are performed as necessary before the child starts school (4 to 5 years of age). A final septorhinoplasty or lip revision, or both, is performed when children have completed growth, generally in the late teen years, at which time the deviated nasal septum and asymmetrical nasal bones or lip (or both) are reconstructed.

#### **Orthodontics/Cleft Alveolus Management**

Orthodontics may be started as early as 3 to 4 years of age and continue through the teen years. The teeth adjacent to the cleft site may be missing, misshapen, or misaligned. In some cases, teeth may need to be passively molded or even extracted. Patients for whom no gingivoperiosteoplasty was performed or for whom gingivoperiosteoplasty failed, orthodontics are applied before secondary alveolar bone grafting. This procedure involves cancellous bone harvested from the iliac crest and grafted into the alveolar cleft site to allow complete ossification of the alveolar arch and to allow preservation of the canine tooth. Some surgeons advocate primary bone grafting in infancy (in which case a small piece of rib is used), although most surgeons perform the alveolar bone graft as needed in children between 7 and 9 years of age during the mixed dentition period.

#### **Orthognathic Surgery**

Orthognathic surgery (surgery of the jaws [maxilla, mandible, or both]) is sometimes needed to align the jaws in a normal occlusal relationship. Children with clefts often have maxillary retrusion caused by intrinsic maxillary deficiency or from scarring resulting from surgical repair. A maxillary advancement (LeFort I osteotomy, Figure 229-11) may be performed by distraction osteogenesis in school-aged children or through the more traditional advancement osteotomy with rigid titanium plate fixation in the teenage years. In some cases, the mandible is set back to meet the maxilla. Factors considered in timing orthognathic surgery include upper airway obstruction, sleep apnea, malocclusion, articulation errors, masticatory problems caused by malocclusion, and the psychosocial effects of facial disharmony. Final prosthodontic care, including dental implants or bridges, may be needed for missing or malformed teeth around the cleft site in the late teenage years.

#### **Pierre Robin Sequence**

Pierre Robin sequence consists of micrognathia, glossoptosis, and upper airway obstruction, with or without cleft palate. An infant with a small mandible and upper airway obstruction should be placed in the prone position to allow the tongue to fall forward out of the pharynx and should be kept on a pulse oximeter to assess his or her oxygen saturation. If this conservative measure is not adequate to alleviate the obstruction and maintain oxygen saturations above 94%, then a nasal trumpet may be placed (12 or 14 French). If necessary, the baby may be bag-ventilated with a jaw thrust, nasal trumpet, or oral airway in

**Figure 229-11** A, LeFort I distraction osteogenesis, preoperatively. B, LeFort I distraction osteogenesis, postoperatively.

place and endotracheal or nasotracheal intubation carried out in a controlled environment by the medical staff. If necessary, the tongue may be pulled forward with a piece of gauze between the fingers or, rarely, a towel clamp.

Further workup for these infants includes a 3-dimensional craniofacial computed tomographic scan to evaluate the size of the mandible and the position of the tongue in the pharynx and to rule out choanal atresia and other anomalies, nasoendoscopy to evaluate the position of the tongue in the pharynx with spontaneous respirations, and direct laryngobronchoscopy to rule out other airway anomalies (laryngomalacia or tracheomalacia). Infants with Pierre Robin sequence may also have gastroesophageal reflux disease and should be evaluated and treated as necessary. A polysomnogram may be performed if the child is stable enough. Newborns with Pierre Robin sequence may be unable to feed adequately with a bottle because of their airway obstruction and may have to be fed through a nasogastric tube or syringe until more definitive treatment is carried out.

Indications for surgical intervention include continued upper airway obstruction and oxygen desaturation such that the baby cannot be taken out of the prone position, need for nasal trumpet or intubation, an abnormal apnea-hypopnea index on sleep study, inability to be fed with a bottle, and failure to thrive. The 2 most common surgical interventions include mandibular distraction osteogenesis and tongue-lip adhesion; other operations include subperiosteal release of the floor of the mouth and tracheostomy for the most severe cases.

Mandibular distraction osteogenesis involves lengthening the mandible using either internal or external devices. The mandible is distracted 1.0 to 1.5 mm/day until the mandible is in a normal or over-corrected position and the airway obstruction and feeding difficulties are alleviated. The regenerated bone consolidates within 6 to 8 weeks, and the distractors are removed. Complications include device failure, possible tooth bud damage or inferior alveolar nerve paresis, and poor scar formation. Future growth of the mandible is unknown at this time because distraction osteogenesis does not have sufficient long-term follow-up.

Tongue-lip adhesion involves suturing a flap of muscle and mucosa from the undersurface of the tongue to a similar flap on the inner surface of the lower lip to prevent tongue base prolapse, which results in airway obstruction. Complications include a dehiscence, inability to feed with a bottle, and failure to alleviate the upper airway obstruction. The tongue-lip adhesion is reversed (usually at about 9 to 12 months of age) to allow normal oral-motor coordination for speech and swallowing, after the mandible has grown sufficiently such that the tongue base no longer obstructs the airway. The cleft palate is repaired during the tongue-lip adhesion reversal operation as well.

## CONCLUSION

The child with a cleft should be followed closely from before birth through adulthood by a multidisciplinary team. Successful treatments result in a well-adjusted child with normal facial harmony, dental occlusion, speech, and hearing.

**WHEN TO REFER****Prenatally**

- Refer to plastic surgery, otolaryngology, genetics, and nursing specialists to provide appropriate counsel for what is to be expected postnatally.

**From birth until 3 to 4 months of age**

- Audiologic evaluation
- Ear-nose-throat evaluation for middle ear disease
- Possible orthodontic evaluation for the use of presurgical orthopedics
- Surgical management with cleft lip and nose repair

**9 to 12 months of age**

- Palate repair
- 2 to 8 years of age
- Speech evaluation and therapy with or without surgical management of velopharyngeal insufficiency

**Late childhood and teen years**

- Alveolar bone grafting as needed
- Lip and nose revisions as needed
- Orthodontics and orthognathic surgery as needed

**Chapter 230****COAGULATION DISORDERS**

Michael U. Callaghan, MD; Madhvi Rajpurkar, MD

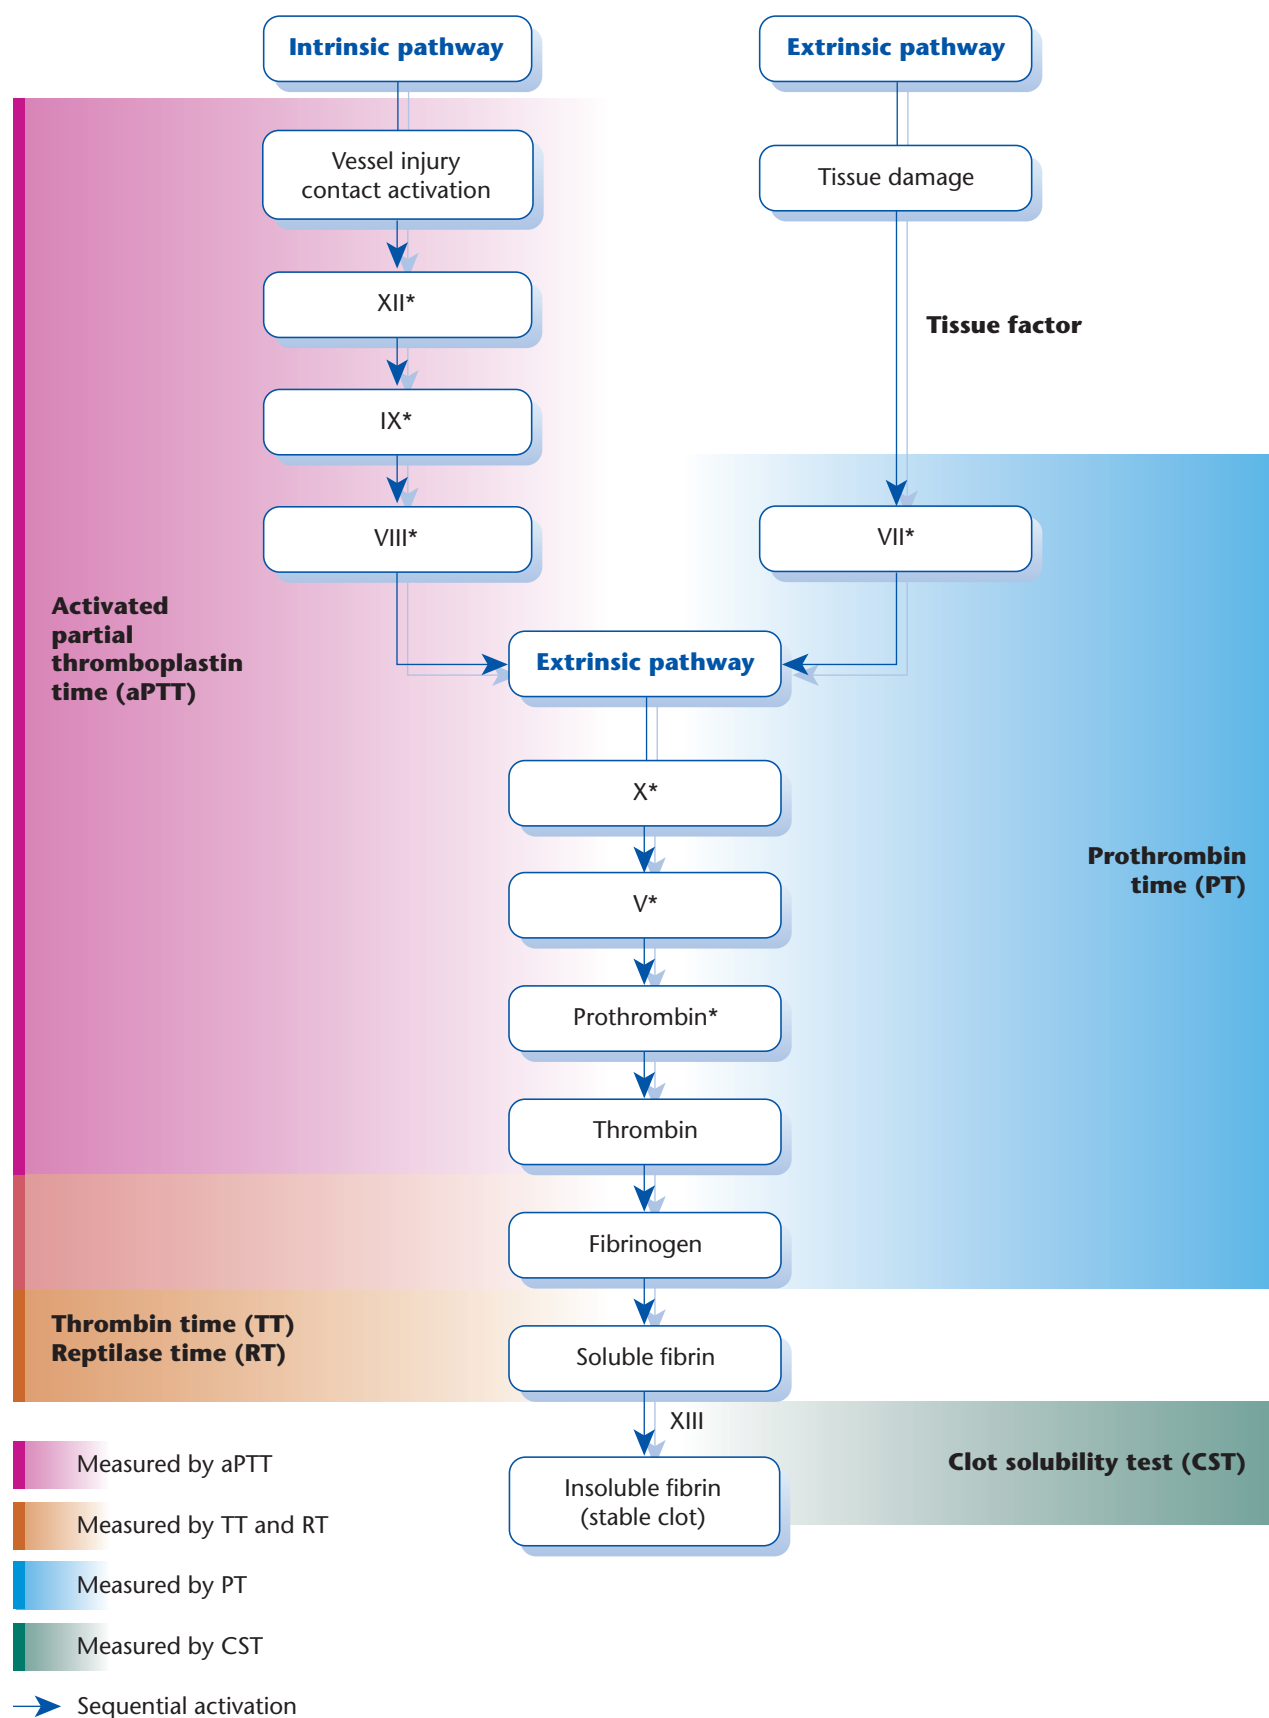

Hemostasis is vital for maintaining the integrity of the high-pressure vascular system. The functions of the coagulation system go far beyond just blood

clotting. The hemostatic system plays an important role in tissue healing, growth, and inflammatory responses. Blood coagulation requires adhesion of platelets to an injured vascular endothelium and aggregation of additional platelets with the formation of a platelet plug. This leads to activation of coagulation factors, resulting in the formation of a fibrin clot that interacts with the platelet aggregate to form a stable hemostatic seal. Coagulation and fibrinolysis are complex physiologic processes that involve interactions between plasma proteins, platelets, leukocytes, phospholipids, and endothelial cells. In mammalian blood, coagulation is intimately linked to and followed by fibrinolysis (the process of fibrin degradation), which is essential for maintenance of patent vascular and circulatory systems. The coagulation factors and the fibrinolytic factors exist in the blood mostly as zymogen precursors that become activated to become enzymes or cofactors and, in turn, activate other clotting factors (Figure 230-1).

**EVALUATION TO DETECT ABNORMALITIES OF HEMOSTASIS**

A pediatrician is often faced with the decision to evaluate patients who have unusual, spontaneous, prolonged, or delayed bleeding. As in any other field of medicine, when a physician is confronted with a child with a possible bleeding disorder, a detailed assessment of the patient's bleeding history and a physical examination guide appropriate laboratory studies. Normal "childhood-pattern bruising" needs to be differentiated from pathologic bruising. The pattern of childhood bruising is often related to the degree of mobility. Bruising in babies who are not able to walk is very uncommon (<1%) and, if present, should be evaluated for coagulation disorders or non-accidental trauma. Bleeding disorders are clinically indistinguishable from abusive bruising in immobile, young children. All immobile, young children with bruising and no reasonable history should be evaluated for the presence of a bleeding disorder and nonaccidental trauma simultaneously. On the other hand, most school-aged children have bruises that are generally small, sustained over bony prominences, and found on the front of the body. A detailed history should also specify the site of bleeding, the age at which bleeding was first noticed, the severity, and the triggers for bleeding. A detailed history of medications and previous hemostatic challenges in the form of bleeding after surgeries and dental procedures should also be sought. The extent to which one investigates bleeding should always be guided by the clinical history. It is also important to take a complete family history as part of the bleeding evaluation, not just a personal history of the patient. Recently, bleeding assessment questionnaires and tools have been developed and are being validated in children.

Additionally, a detailed family history of bleeding should be obtained. Hemophilia A and hemophilia B are X-linked recessive disorders, and a history of a similar bleeding pattern in other male members may suggest their presence. However, the absence of a family history should not deter a physician from

**Figure 230-1** Sequential activation of zymogen cofactors results in conversion of fibrinogen to an insoluble clot. aPTT measures activity of intrinsic and common pathways; PT measures extrinsic and common pathway; TT and RT measure clottable fibrinogen; CST detects very low factor XIII activities. \*Factors become activated and, in turn, propagate the cascade.

further investigations because spontaneous mutations causing hemophilia are seen in 30% to 40% of patients with hemophilia. On the other hand, most other clotting factor deficiencies are inherited in an autosomal-recessive pattern, and a history of consanguinity may be helpful. Von Willebrand disease (vWD) is also inherited, and family members may be affected. The most common type, type 1 vWD, has an autosomal-dominant pattern of inheritance, but may have variable expression in affected members.

A properly drawn blood sample is crucial for proper interpretation of results of coagulation tests. Blood for coagulation assays should be obtained by clean venipuncture without air bubbles and without contamination with tissue fluids. In general, drawing of the sample from indwelling catheter often results in sample contamination with heparin or intravenous fluids and thus spuriously abnormal values. Improper sample collection is one of the most common reasons for falsely elevated clotting times.

The usual screening tests are a complete blood count with review of the morphology of the peripheral blood. An activated partial thromboplastin time (aPTT) and prothrombin time (PT) can also be obtained. Falsely prolonged clotting times may result from an insufficient amount of blood in the specimen tube or difficulty accessing the vein with release of tissue factor and consumption of coagulation factors. The tests are sensitive to clotting factor levels less than 30% to 40% of normal. If the PT or aPTT is prolonged, either repeating the tests or referral to a specialist may be indicated based on the presence and severity of the bleeding symptoms.

### Prothrombin Time

The PT is performed by adding a thromboplastin reagent containing calcium chloride to the citrated plasma sample. The time required for clot formation is recorded using an automated instrument that signals the endpoint, as defined by optical or electromechanical change. The normal (reference) range varies depending on the laboratory (its instrumentation and the lot of thromboplastin), but is generally 10 to 11 seconds. The PT measures the activities of factors I (fibrinogen), II (prothrombin), V, VII, and X. Prolongation of the PT beyond the reference range is generally not seen until the functional level for one of these factors is less than 30% or until fibrinogen is less than 100 mg/dL. An isolated prolongation of the PT may reflect factor VII deficiency. Although rare, the PT can also be prolonged by a circulating inhibitor or by the presence of abnormal fibrinogen molecules or D-dimer fragments in the circulation.

The PT is also quite useful for monitoring the effect of coumarin-type anticoagulants. When the PT is used to monitor a patient on warfarin, the differences in the sensitivities of the thromboplastin need to be taken into account. This has led to the development of a standardized method of expressing the prolongation as an international normalized ratio (PT-INR). The INR is calculated as  $INR = (\text{patient's PT}/\text{control PT})^{\text{International Sensitivity Index (ISI)}}$ . The ISI should be determined for each thromboplastin reagent and instrument.

### Activated Partial Thromboplastin Time

The aPTT is performed by adding a “partial thromboplastin” reagent, which is a source of phospholipids without tissue factor, to the patient’s citrated plasma sample, plus introducing controlled activation of the contact factors (factors XI and XII, prekallikrein, and high-molecular-weight kininogen) by preincubation with a surface-activating reagent (eg, celite, kaolin, silica, or ellagic acid). This mixture is incubated for 2 to 5 minutes before calcium chloride is added, and the time required for clot formation is recorded. As for the PT, automated instruments are generally used. The aPTT measures factors I (fibrinogen), II (prothrombin), V, VIII, IX, X, XI, and XII; prekallikrein; and high-molecular-weight kininogen. Deficiency of any of the latter 3 factors can result in a markedly prolonged aPTT in the absence of clinically significant bleeding. Isolated prolongation of the aPTT in a patient with clinical bleeding is likely to result from a deficiency of factor VIII, IX, or XI. It should be noted that the sensitivity and reproducibility of the aPTT are highly dependent on the specific reagents used (particularly the activator in the partial thromboplastin reagent). The laboratory should establish a reference range for each new lot of reagent and each new method of clot detection. The reference range will generally be approximately 26 to 35 seconds for children and adults, but longer (30 to 54 seconds) in term infants, and often even longer in premature infants.

The aPTT is somewhat less sensitive than the PT to the deficiency of vitamin K-dependent factors, but is more sensitive to the presence of circulating anticoagulants and heparin. The aPTT can detect circulating anticoagulants (such as lupus anticoagulants) and is routinely used to monitor standard heparin therapy. Among hospitalized infants or children, unintentional contamination of patient samples with heparin is a common cause for an unexpected prolongation of the aPTT that does not correct on mixing.

### Thrombin Time

The thrombin time (TT) measures the thrombin-induced conversion of fibrinogen to fibrin and is performed by adding bovine thrombin to the patient’s citrated plasma and recording the clotting time. The TT measures the amount and the clotting function of fibrinogen and is also prolonged in the presence of heparin or circulating fibrin degradation products. An extremely prolonged TT usually indicates a heparin effect. The snake venom protease, reptilase, clots fibrinogen in the presence of heparin and can be used to identify heparin as the cause of the prolonged TT. Thus, in the presence of heparin, the TT is prolonged while the reptilase time is normal. Alternatively, one can test for heparin activity by its anti-factor Xa activity or with the use of commercial heparinase. The sensitivity of the TT can be increased by dilution of the thrombin to give a control thrombin clotting time (TCT) of 16 to 18 seconds.

Normal values differ from 1 laboratory to another and between instruments and reagents. Thus, obtained values should be compared with the normal range for that laboratory. Additionally, in children, the normal values for coagulation and anticoagulant

proteins differ with age. Thus, the values obtained should be compared with normal values for the age of the patient.

The bleeding time, once considered to be a useful screening test for vWD, is difficult to standardize with poor sensitivity and specificity and high interobserver and intraobserver variations. It has been replaced in many centers by the platelet function analyzer (PFA-100), a screening test using a commercially available instrument. The test is quantitative, simple, rapid, and reproducible and measures, under high shear stress, the time taken for a platelet plug to occlude a microscopic aperture in a membrane coated with platelet agonists. However, it lacks the sensitivity for mild vWD and platelet disorders. Thus, if the history is suggestive, performing vWD level analysis or formal platelet aggregation tests may be appropriate.

## HEMOPHILIA A AND B

Hemophilia A (deficiency of factor VIII, or antihemophilic factor) and hemophilia B (deficiency of factor IX, or Christmas factor) are X-linked recessive disorders with similar clinical manifestations with an estimated incidence of 1:10,000 and 1:30,000 males, respectively. A positive family history is seen in approximately two-thirds of the patients, and in one-third of the patients there are new mutations. Hemophilia A and hemophilia B occur worldwide with no racial predilection.

## DIAGNOSIS

The diagnosis can often be suspected based on family and personal history of bleeding. Laboratory studies often show a prolonged aPTT with a normal PT and normal tests for platelet function. Specific factor assays for factors VIII and IX identify the deficiency. Severe hemophilia accounts for 80% of cases of hemophilia A and 60% of cases of hemophilia B and is defined by a factor VIII or IX level lower than 1%. Levels between 5% and 40% are associated with mild disease, and levels between 1% and 5% are associated with moderate disease. It is important to diagnose the severity of the disease accurately because spontaneous bleeding is common in severe hemophilia, whereas patients with moderate to mild hemophilia have trauma-induced bleeding. In most families, diagnosing hemophilia prenatally is now possible by chorionic villus biopsy or amniocentesis. The factor VIII and factor IX genes have both been cloned, and many different mutations have been identified in both conditions.

## Bleeding Manifestations

### Hemarthrosis

Recurrent bleeding into joints is the hallmark of patients with severe hemophilia. The knees, ankles, and elbows are commonly involved, but bleeding can occur in any joint. Hemarthrosis must be treated as soon as pain, tingling, or limping begins, even if evidence of swelling is not visible. Watchful waiting is not appropriate for the child who has moderate or severe hemophilia. Prompt replacement of either factor VIII or factor IX should be continued until signs of joint swelling resolve. Primary prophylaxis before the first bleed is an effective therapy for reducing joint bleed-related morbidity; and after a joint bleed occurs in a patient

with hemophilia, factor prophylaxis given twice or thrice a week should be strongly encouraged. The difficulties of intravenous access often interfere with starting prophylaxis early, and central venous access devices may be considered to circumvent this issue.

Many patients with hemophilia have a particular target joint in which recurrent episodes occur and in which chronic changes are most likely to result. Synovial thickening and vascular friability may develop, resulting in increased susceptibility to bleeding. Synovitis accompanied by chronic effusion often develops and may progress to joint destruction (hemophilic arthropathy) and severe disability. With prompt, adequate treatment or prevention of bleeding, the incidence of these complications is significantly decreased. Synovectomy may be effective if medical management fails and may be accomplished by open, arthroscopic or radionuclide approaches. Intensive physical therapy is required in conjunction with the procedures. Radiosynovectomy is a simpler procedure, requiring less factor replacement and physical therapy. Although this procedure has been performed in young children with good joint outcomes, some concern exists about the possibility of inducing malignancy.

### Soft Tissue Bleeding

Superficial hematomas, unless very large, do not often require treatment. However, bleeding into muscles or closed soft tissue compartments may result in nerve or vascular compression, muscle fibrosis, and contractures; such bleeding may be difficult to diagnose because swelling is often minimal. Bleeding into the iliopsoas muscle may cause femoral nerve damage, and it must be considered whenever pain occurs in the lower abdomen, hip, or groin. Limping and flexion of the hip are often the only positive findings. Sonography or computed tomography (CT) may help in making the diagnosis. Because the iliopsoas represents a large potential space, patients can lose enough blood to compromise perfusion and induce shock before obvious symptoms develop, so the index of suspicion for iliopsoas bleeding must be high and the threshold for therapy and imaging low in the setting of vague abdominal pain. Calf bleeding may result in peroneal nerve damage. Bleeding into the thigh may cause accumulation of a large amount of blood without much external change and may result in significant anemia.

### Life-Threatening Bleeding

Intracranial bleeding can occur after trauma or spontaneously. All but the most minor head injuries must be considered to be significant and treated promptly. Appropriate imaging should be considered based on the age of the child. In the newborn period, an ultrasound may be obtained; in older children, a CT scan of the head may be more appropriate. It is important to treat with factor replacement before obtaining imaging studies because delay in therapy may have an adverse outcome.

Airway compromise must be considered a potential threat with any hematoma of the neck or the submental or sublingual areas, as well as the retropharyngeal

or parapharyngeal regions; a severe sore throat or dysphagia also suggests bleeding and should be evaluated and treated immediately. Retroperitoneal bleeding may be massive before it can be detected and must be considered when abdominal or groin pain is present. In these situations, CT or magnetic resonance imaging may be helpful in evaluating the patient.

### **Mouth Bleeding**

The lip, tongue, and frenulum are areas of frequent trauma in mobile young children. Additionally, although epistaxis is not common in hemophiliac patients, the amount of blood loss can be significant and can often result in iron deficiency. Factor replacement should be accompanied by the use of  $\epsilon$ -aminocaproic acid or tranexamic acid to prevent fibrinolysis of the clot, although these drugs must be used cautiously in patients receiving prothrombin complex or any activated coagulation factors because the combination can lead to thrombosis or disseminated intravascular coagulation (DIC).

### **Hematuria**

Hematuria must be evaluated with noninvasive procedures, as in the normal individual, to rule out intrinsic renal disease. It usually resolves spontaneously with or without factor replacement, although bed rest and hydration are often suggested. Fibrinolytic agents and factor replacement should be avoided, unless the bleeding is known to originate in the lower urinary tract, because they can result in obstruction of the renal pelvis by clot formation. The role of steroids in the treatment of hemophilia hematuria is controversial, but is likely not beneficial.

## **GENERAL PRINCIPLES OF TREATMENT**

Ideal management of patients who have hemophilia is in a comprehensive hemophilia treatment center where all the needs of the patient can be met, including medical, orthopedic, physical rehabilitation, dental, and psychosocial therapies. All elective surgical procedures must be performed in a center that has experienced personnel, immediate availability of blood clotting factor assays, and a ready supply of clotting concentrates, and they should be preceded by evaluation for factor inhibitors. Nerve blocks, intramuscular injections, and arterial blood draws should be avoided. In general, antiplatelet medications, such as aspirin and other nonsteroidal anti-inflammatory drugs, should be avoided. Factor replacement should always be given as promptly as possible when bleeding is suspected, before radiographic examination or other diagnostic studies are performed. A patient who has a severe injury or life-threatening bleeding should be given an immediate dose of the appropriate clotting factor to raise its level to 100% and then be transferred to a hemophilia center.

Any significant injury must be treated promptly, even without apparent evidence of active bleeding, given that bleeding is often delayed. A small, superficial laceration, if not bleeding or in need of cleaning or sutures, may be managed with a simple pressure dressing; however, if bleeding occurs or if suturing is

required, then the appropriate clotting factor must be administered immediately. Casts should not be applied unless factor has been administered beforehand and is continued for several days afterward; the involved area should be watched closely for evidence of nerve or vascular compression. Factor replacement must be provided before all surgical procedures, arterial punctures, and lumbar punctures.

Pain should be managed on acetaminophen whenever possible; however, codeine and other oral narcotics can be provided if necessary. Although aspirin must be avoided, nonacetylated salicylates (eg, choline magnesium trisalicylate) can be used, and nonsteroidal anti-inflammatory agents such as ibuprofen can be given cautiously if the patient is not also receiving zidovudine. Although cyclooxygenase-2 inhibitors showed early promise as analgesic agents for patients with hemophilia, cardiovascular toxicity that led to the withdrawal of rofecoxib from the market suggests that these drugs should not be used routinely until more is known about them. Ketorolac may be more effective for the treatment of musculoskeletal and joint pain. Treating bleeding episodes as early as possible helps to limit severe pain so that the need for narcotics can be minimized.

### **Factor Replacement**

Products available for the treatment of coagulation disorders are described in Table 230-1. Whole plasma can raise factor VIII levels to only 40% and factor IX levels to 20% because of the large volume and protein load that accompany its use. Early in the acquired immunodeficiency syndrome (AIDS) epidemic, experts suggested that plasma or cryoprecipitate be provided when possible, rather than concentrates made from large donor pools. However, the safety of current concentrates makes them the preferred mode of treatment in most situations. Recombinant factors VIII and IX are available and effective and seem to be free of viral contamination. Some studies have indicated an increased incidence of inhibitor development with these products, although other studies have not agreed with this finding. Factor IX is available in the form of prothrombin complex, as well as in purified and recombinant forms. Although mild bleeding requiring a single treatment can be managed with the complex, this approach has a danger of thrombosis or DIC from activated factors in the complex, particularly in patients with liver disease. The cost of these products increases with the degree of purification. The Medical and Scientific Advisory Committee of the National Hemophilia Foundation recommends the use of recombinant factor products when available because of the decreased risk for viral infections. Generally, a patient should be treated when possible with only 1 brand of factor product, and switching products should be minimized because it may be associated with inhibitor development.

The desired levels of factor VIII or IX for managing different clinical problems are listed in Table 230-2. Preassayed concentrates are available in vials containing varied doses. Whole vials containing the calculated, desired dose or a higher level should be given because these products are too expensive to waste.

**Table 230-1** Products Available for Treatment of Coagulation Disorders

PRODUCT	CONTENT	DOSE, CONCENTRATION, SIZE OF UNITS	INDICATIONS, COMMENTS
Fresh frozen plasma	Whole plasma	5–15 mL/kg; 1 U of each of the coagulation factors/mL; 220 or 600 mL/bag	Multiple factor deficiency; DIC; reversal of Coumadin effect; HUS or TTP; unknown coagulation defect; when no specific concentrate exists; not virus inactivated
Cryoprecipitate	Factor VIII, factor XIII, fibrinogen, fibronectin	1 U/kg raises factor VIII 2%; 75–100 U factor VIII and WF/bag; volume approximately 20 mL; not assayed	Factor XIII deficiency, hypofibrinogenemia; derived from single-donor units; not virus inactivated
Factor VIII	Factor VIII	1 U/kg raises factor VIII 2%; preassayed; up to 100 U/mL	Hemophilia A; made by various methods, with different levels of purification; recombinant product available; virus inactivated <sup>a</sup>
Humate P	Factor VIII, vWF	Preassayed; factor VIII 20–40 U/mL; 50–100 U/mL	Severe vWD; mild to moderate vWD if DDAVP ineffective or inadequate; virus inactivated <sup>a</sup>
Factor IX	Factor IX	1 U/kg (1.2–1.4 U/kg of recombinant) raises factor IX 1%; preassayed; up to 100 U/mL	Hemophilia B; recombinant product available; virus inactivated <sup>a</sup>
Prothrombin complex	Factor II, VII, IX, X	Preassayed for factor IX; content of other factors varies among products	Hemophilia B when purified factor IX cannot be used; mild bleeding in hemophilia A with inhibitor; congenital deficiency of factor II or X; danger of thrombosis (including MI and DIC) in presence of liver disease, prolonged use; virus inactivated <sup>a</sup>
Activated prothrombin complex	Factor II, VII, IX, X; factor VIII <i>bypassing</i> activity	Preassayed for ability to shorten aPTT of plasma with high-titer factor VIII inhibitor	Hemophilia A or B with inhibitor; cannot evaluate response by measuring factor VIII activity; risk for DIC and thrombosis
NovoSeven	Recombinant factor VIIa	Preassayed	Hemophilia A or B with inhibitor; factor VII deficiency; risk for thrombosis

aPTT, activated partial thromboplastin time; DIC, disseminated intravascular coagulation; HUS, hemolytic uremic syndrome; MI, myocardial infarction; TTP, thrombotic thrombocytopenic purpura; vWD, von Willebrand disease; vWF, von Willebrand factor.

<sup>a</sup>Virus attenuation processes may not inactivate parvovirus, hepatitis A, and possibly other viruses.

Continuous infusion can be used for patients who are undergoing surgery or who are bleeding extensively.

### Health Care Maintenance

Routine immunizations, which must include hepatitis B and hepatitis A vaccines, should be given subcutaneously, if possible, with a 25-gauge needle; pressure should be maintained for 5 to 10 minutes. Although the effectiveness of hepatitis A vaccine administered subcutaneously is clearly good, this is less clear for other vaccines. Intramuscular injections are controversial, but are probably safe when a small needle

(23 gauge or less) is used and pressure is held for 1 to 2 minutes. Intramuscular injections can also be scheduled after routine factor replacement in patients on prophylaxis. Routine dental evaluation, prophylaxis, and hygiene should begin by 3 years of age. The most difficult part of managing the child who has hemophilia is to use appropriate caution, but, at the same time, allow for the development of independence. Family education about the disease is essential, and support groups are beneficial. These patients and their families should be closely monitored for psychosocial issues. Not only do they have to live with a serious

**Table 230-2 Treatment of Bleeding Episodes in Hemophilia**

TYPE OF BLEEDING	DESIRED LEVEL OF FACTOR VIII OR IX	DURATION OF TREATMENT	ANCILLARY TREATMENT
Hematoma, simple	20%–40%	Usually once	—
Hemarthrosis, mild muscle hematoma	30%–40%	Once, as soon as symptoms begin; if severe, repeat daily until better clinically.	Non-weight bearing and rest; gradual initiation of passive physical therapy; pain control
Severe muscle hematoma	50%–100%	3–7 days	Check hemoglobin because large hematomas may cause anemia; non-weight bearing and rest; gradual initiation of passive physical therapy; pain control
Mouth bleeding, epistaxis, dental extractions	80%–100%	Once	Start EACA 75–100 mg/kg every 6 hr or tranexamic acid 25 mg/kg every 6–8 hr by mouth for 3–7 days (until clot is gone)
Gastrointestinal bleeding	100%	3–7 days	EACA or tranexamic acid
Hematuria	Factor may not be needed	3–7 days	Bed rest; hydration; do not use EACA
Life-threatening, central nervous system, airway obstruction, retroperitoneal	100%; do not allow drop <50%	7–14 days	Monitor factor and inhibitor levels
Surgery	100%; do not allow drop <50%	7–14 days	Preoperative inhibitor testing; monitor levels
Prophylaxis	20–40 U/kg	3 times per week for factor VIII; 2 times per week for factor IX	Demonstrated to improve joint outcomes

EACA, *ε*-aminocaproic acid.

A total of 1 U/kg of factor VIII increases plasma level by 2%; biologic half-life = 10–12 hours. A total of 1 U/kg of factor IX increases level by 1%; 1 U/kg of recombinant factor IX increases level by 0.8%; biologic half-life = 20–24 hours. Slightly lower levels of factor IX than of factor VIII are effective.

Initial dose = 50 U/kg of factor VIII and 80–100 U/kg of factor IX; repeat one-half the factor VIII dose in 8–12 hours and one-half the factor IX dose in 12–24 hours, or provide a continuous infusion of 3–4 U/kg/hr of either factor VIII or factor IX after initial bolus dose.

chronic illness associated with frequent pain and limitation of normal activities, but also the effect of AIDS on the adult population has been devastating and, in many cases, has eroded trust in medical caretakers. Additionally, the cost of hemophilia therapy often presents unique difficulties for patients obtaining and maintaining insurance. Counseling around this topic is essential.

There is an important implication for future pregnancies to the families of children diagnosed with hemophilia, vWD, or other congenital factor deficiencies. Because these are inherited conditions (although in hemophilia, there can be spontaneous mutations), screening other family members may be appropriate. Referral to a geneticist specializing in bleeding disorders may be appropriate, especially to identify carriers and to counsel them regarding future pregnancies.

### Home Management

If a child has reasonably easy venous access and family dynamics permit it, then parents can be taught to administer treatment to children as young as 3 years of age, and 9- or 10-year-olds can be taught to self-administer factor concentrates. This approach allows for much earlier treatment of bleeding episodes, provides the satisfaction of self-sufficiency, and

prevents some of the frustrations of having to get to a treatment center or emergency department. Indwelling venous access devices are being used with increasing frequency and have simplified home, as well as in-hospital, management, although infections and thrombosis have been problems with these devices. Home intravenous therapy is also a convenient way to administer prophylaxis or immune tolerance induction. Before initiation of home therapy, caregivers should receive adequate education and training and perform infusions under the supervision of medical staff until proficient and comfortable with the technique.

### Mild Hemophilia

The patient who has mild hemophilia is more likely than the patient with severe disease to receive inadequate treatment of bleeding episodes because neither the family nor the physician may be aware of the need for treatment. Significant injuries in patients with mild hemophilia require management similar to those with severe disease, although smaller doses of factor concentrates may be sufficient to attain the desired factor levels. Desmopressin (DDAVP) is a vasopressin analog that results in release of factor VIII from the endothelial cells where it is produced,

resulting in almost a threefold increase of the level. It may, therefore, be effective if the baseline factor VIII level is more than 5%, depending on the level desired. Overhydration must be prevented because water retention and hyponatremia may occur with DDAVP therapy, particularly in young children and with repeated doses. A concentrated intranasal preparation is available and has been used in children 6 years of age and older. A stimulation test with response assessment should be performed in each patient with either intravenous or nasal preparations before they are used therapeutically for the first time. The response to DDAVP often correlates with the underlying genetic mutation causing hemophilia and the age of the patient. Although DDAVP response has been tested in infants as young as 11 months of age, there is no consensus on the optimal age for testing the DDAVP response. Because of concerns of hyponatremia and of the possibility of a lack of response at a younger age, most centers wait until the patient is older than 3 years for the DDAVP challenge. DDAVP is ineffective in factor IX deficiency.

### Prophylaxis

Prophylactic factor concentrate treatment administered several times a week is considered to be the optimal care for children who have severe hemophilia to prevent hemarthrosis and joint damage and to normalize their lives. Although this form of treatment is more expensive than episodic treatment for bleeding, the additional cost saving by preventing future orthopedic complications is considerable. The psychological benefits also must be considered. Children who have moderate hemophilia and behave like mild cases are treated similarly to children with mild hemophilia. Those who have spontaneous bleeding (often with levels of 1%–3%) are most often treated as severe cases.

### Inhibitors

Approximately 30% of patients who have severe hemophilia A and 3% who have hemophilia B develop antibodies that inhibit factor VIII or factor IX activity, usually early in their treatment, although many of these antibodies are present in low titer and may subsequently disappear. Such patients should be managed only by experienced physicians. Inhibitor antibodies are more common in patients with severe hemophilia, those with large gene deletions, and those with a family history of inhibitors. Most inhibitor antibodies develop before the 20th infusion of factor products, but they can develop at any time. Management may include the use of large doses of factor VIII or factors that bypass factor VIII in the coagulation cascade (prothrombin complex, activated prothrombin complex, recombinant factor VIIa) or the use of porcine factor VIII. Induction of immune tolerance by continuous exposure to high doses of factor over many weeks to months, with or without concomitant immunosuppression, has been found to be effective in controlling the inhibitor in most cases. An inhibitor should be suspected if the response to appropriate therapy is inadequate, and it should be sought regularly in all patients and before all elective surgery. A Bethesda inhibitor assay will determine the presence

and strength of an inhibitor. Patients who have hemophilia B with inhibitors may develop anaphylaxis or nephrotic syndrome when given factor IX. Management is much more difficult than for hemophilia A, but recombinant factor VIIa has been effective. Because of the incidence of life-threatening anaphylactic reactions in hemophilia B, the first 20 to 30 factor infusions should be administered in a medical facility capable of treating anaphylaxis.

### Acquired Immunodeficiency Syndrome and Other Viral Infections

Most patients who had severe hemophilia in the United States in the late 1970s and early 1980s became infected with HIV. The treatment of hemophilia with clotting factor concentrates from large donor pools in the era before the virus was identified resulted in massive exposure to HIV. Chronic liver disease has also been a major problem, most often caused by hepatitis C and sometimes by hepatitis B virus infection. Currently, both donor testing and several methods to inactivate viruses in the production process make the concentrates safe with regard to HIV. Hepatitis B and C have also been largely eliminated. (See Chapter 59, Blood Products and Their Uses.) The increasing availability and use of recombinant factors may eliminate the problem of viral infections.

### Gene Therapy

Although gene transfer of both factor VIII and factor IX genes has been accomplished in several animal models, as well as in a small number of clinical trials, the results have been disappointing. In addition, concerns about the possibility of inducing malignancy or liver disease remain. However, investigations into this modality of therapy continue to be pursued.

### VON WILLEBRAND DISEASE

Von Willebrand disease is the most common hereditary coagulation disorder, with estimates of an incidence as high as 1% of the population, although most of these individuals are asymptomatic and the incidence of symptomatic is probably closer to 1 in 10,000 individuals. Von Willebrand factor (vWF) is the carrier protein for factor VIII and exists in a series of different-sized multimers of smaller subunits. Additionally, vWF acts as a bridge between the platelet and the damaged endothelium and is important for platelet adhesion. Decreased vWF is associated with a corresponding decrease of factor VIII activity and decreased platelet function in most cases. The inheritance is usually autosomal dominant with variable penetrance, but autosomal-recessive variants occur. The gene is on chromosome 12 and has been cloned, and many genetic mutations have been identified. In addition to bleeding after surgery and trauma, the major manifestation of vWD is mucosal bleeding, which most frequently exhibits as epistaxis. Menorrhagia and, less commonly, gastrointestinal bleeding also may occur. Hemarthrosis and deep hematomas may be seen in severe (type 3) vWD. Several components of the vWF-factor VIII complex and function can be determined: factor VIII activity, vWF activity (ristocetin cofactor, vWF:RCO), vWF antigen (vWF:Ag), and the pattern of

multimers. In hemophilia, the vWF is normal. Many variants of vWD exist. The most common is type 1, in which all components are similarly reduced and the multimer pattern is normal. Type 2 results from qualitative defects in vWF and can include decrease or absence of the larger multimers; type 2B exhibits increased binding to platelets. Type 2N results from impaired binding of factor VIII and resulting low factor VIII levels and can be misdiagnosed as mild to moderate hemophilia A. Type 2N should be considered in the differential diagnosis of mild or moderate hemophilia A, particularly in the absence of family history, and is often diagnosed after poor response to factor VIII replacement or when an affected female family member is found to have low factor VIII activity. Type 3 represents severe homozygous deficiency with very low or absent levels of all components.

vWD may be difficult to diagnose. The bleeding time and PFA-100 test are fairly sensitive, but nonspecific, and are prolonged in most patients; most cases are associated with mildly decreased levels of factor VIII. However, the aPTT may be normal if factor VIII is greater than 30% to 40%. All of the studies may be variable, both from patient to patient and in the same patient from time to time. Even if the laboratory test results are normal, they should be repeated if the index of suspicion is high. vWF varies with blood type and with several environmental factors. Levels of 35% to 50% may exist in both patients with vWD and normal individuals with blood type O, making the definitive diagnosis even more difficult. A major differential diagnosis, although much rarer, is one of the disorders of platelet function (see Chapter 181, Petechiae and Purpura).

Most patients who have type 1 vWD will respond to DDAVP as in mild hemophilia A, and this approach can be used for most bleeding episodes. Most patients who have type 2A and all who have type 3 vWD do not respond to DDAVP, and its use is contraindicated in type 2B disease because it may cause platelet aggregation and DIC. A trial dose of DDAVP should be used to assess the response to DDAVP with levels tested before administration and up to 4 hours after dosing because some patients respond poorly and to detect variants with rapid clearance of endogenous vWF. Patients who have severe bleeding or those who do not respond to DDAVP should be treated with a concentrate that contains both factor VIII and vWF. Although fresh frozen plasma or cryoprecipitate can be used, neither is suggested because of the possibility of viral contamination. Mild epistaxis can often be controlled with  $\epsilon$ -aminocaproic acid or tranexamic acid; these agents should also be used as adjunctive therapy for mucosal bleeding other than hematuria.

## OTHER COAGULATION DEFECTS

The other coagulant deficiencies are inherited as autosomal recessive genes with prevalences in the general population varying between 1 in 500,000 and 1 in 2 million for the homozygous forms (see Table 230-3). Factor XI deficiency, afibrinogenemia, and dysfibrinogenemia can be associated with bleeding in both their

heterozygous and homozygous forms. Factor XIII deficiency cannot be detected with the usual screening tests; a normal screening workup in a patient who has a significant bleeding history should be followed with a clot solubility test. The contact factors prekallikrein, high-molecular-weight kininogen, and factor XII are necessary to initiate clotting in vitro; their absence results in a markedly prolonged aPTT, but is not associated with clinical bleeding.

Although all of these deficiencies can be treated with fresh-frozen plasma, concentrates are preferable for treating factor VII deficiency because of its short half-life, as well as other deficiencies when available because they are virus depleted. Recombinant factor VIIa is commercially available. Prothrombin complex products also contain factor VII, as well as factors II and X, but the content of each factor varies in different lots. These products contain activated coagulation factors that may induce thrombosis or DIC, and they must be used cautiously, particularly in patients with liver disease. Fibrinogen and factor XIII are concentrated in cryoprecipitate, and a factor XIII concentrate may be available for compassionate use. Fresh frozen plasma can be used for patients with factor V or XI deficiency or in an emergency for patients who are bleeding but whose deficiency has not yet been identified. Factor XI concentrates are available in some European countries, but not yet in the United States.

### WHEN TO REFER

- All children with hemophilia should be seen at least once a year at a comprehensive hemophilia center if possible
- All elective surgery should be performed at a hemophilia center
- All patients with significant trauma or potentially life-threatening bleeding should be given an initial loading dose of factor (to 100%) and transferred to a hemophilia center
- All patients with inhibitors should be managed at a hemophilia center
- Children with vWD should have an initial evaluation by a specialized coagulation laboratory
- All newly diagnosed patients with a bleeding disorder should be referred to a geneticist for consultation regarding implications and screening (if necessary) in other family members

### WHEN TO ADMIT

- Significant trauma is present
- Bleeding is present in a potentially life-threatening area
- Severe abdominal pain exists
- Any surgical procedure must be performed

## TOOLS FOR PRACTICE

### Engaging Patient and Family

- *What Is Hemophilia?* (fact sheet), National Heart, Lung, and Blood Institute ([www.nhlbi.nih.gov/health/dci/Diseases/hemophilia/hemophilia\\_what.html](http://www.nhlbi.nih.gov/health/dci/Diseases/hemophilia/hemophilia_what.html))

**Table 230-3** Rare Inherited Coagulation Defects

COAGULATION DEFECT	INCIDENCE	INHERITANCE	SEVERITY	TREATMENT
Factor XI	Rare, 5% in Ashkenazi Jews	Autosomal recessive (4q32q3)	Mild to severe	Fresh frozen plasma Half-life 52 hr Factor XI concentrate available in Europe
Prothrombin (factor II)	1:2,000,000	Autosomal recessive (11p11–q12)	Mild to moderate	Prothrombin complex Half-life 60 hr
Factor V	1:1,000,000	Autosomal recessive (1q21–q25)	Mild to moderate	FFP Half-life 15 hr
Factor VII	1:500,000; 1:1,500 mild	Autosomal recessive (13q34)	Mild to severe	Recombinant Half-life 5 hr
Factor X	1:500,000	Autosomal recessive (13q34)	Mild to severe	FFP Half-life 40 hr
Factor XII	Rare	Autosomal recessive 5q33	No bleeding	No treatment
Prekallikrein	Rare	Autosomal recessive 4q35	No bleeding	No treatment
High molecular weight kininogen	Rare	Autosomal recessive 3q27	No bleeding	No treatment
Factor XIII	1:1,000,000	A subunit: 6p24–p25B subunit: 1q31–q32	Moderate to severe	Factor XIII concentrate Cryoprecipitate Half-life 150 hr
Afibrinogenemia	Rare	Autosomal dominant (various mutations at 4q31)	Variable	Cryoprecipitate RiaSTAP
Dysfibrinogenemia	Rare	Autosomal dominant (various mutations at 4q31)	Variable	Cryoprecipitate Anticoagulation if thrombosis
Hypofibrinogenemia	Rare	Autosomal dominant (various mutations at 4q31)	Variable	Cryoprecipitate RiaSTAP (fibrinogen concentrate)
Combined F5 and F8	Rare	Autosomal recessive (18q21, 2p21)	Moderate to severe	Recombinant factor VIII Assess response to Desmopressin (DDAVP)
Combined deficiency of vitamin K–dependent clotting factors	Rare	Autosomal recessive (16q12–q21, 2p12)	Variable	FFP FFP

## Chapter 231

# COLIC

Rebecca Baum, MD

Few events are more overwhelming than bringing a newborn baby home from the hospital. Parents are often filled with excitement, exhaustion, and uncertainty. Imagine the parents' reaction when, once home, their infant begins to experience bouts of inconsolable crying and seemingly cannot be soothed despite their best efforts. This scenario forms the basis for the following review on colic.

### DEFINITIONS

All babies cry, but what is *normal*? In 1962, Brazelton surveyed mothers being cared for in a pediatric practice and showed that healthy newborns experienced a similar pattern of crying. Crying began to increase during the second week of age, peaked at 6 weeks, and decreased in frequency and duration thereafter. At their peak, these healthy babies cried for nearly 3 hours per day, and the episodes of crying often clustered in the evening. Decades later, studies have replicated this pattern of crying in babies in the United States as well as in European and non-European cultures where parenting practices differ. Infants with colic show a similar pattern, but their symptoms are more intense.

The most widely used definition of colic was proposed in 1954 by Wessel et al, who noted that *seriously fussy* babies cried for more than 3 hours a day, more than 3 days a week, and for longer than 3 weeks. This has since become known as the *rule of threes*. Wessel et al characterized the infants' symptoms as "unexplained paroxysms of irritability, fussing, or crying which may develop into agonized screaming. The infant may draw up his knees against his tense abdomen as if there were abdominal pain." Today, modified Wessel criteria are often used, eliminating the stipulation that symptoms be more than 3 weeks in duration. The chronicity of symptoms in babies with colic follows the typical crying curve, starting in the second week, peaking at 6 weeks, and often resolving by 4 months of age. The similarity in the crying patterns between babies with and without colic suggests that colic may represent the upper end of the continuum of *normal* crying.

Especially frustrating for parents is the fact that babies with colic may seem inconsolable during these periods of crying. The infant may continue to cry despite various interventions such as feeding, diaper changes, and soothing techniques. Continued crying can lead to feelings of inadequacy, anxiety, and frustration for parents and caregivers. Parents often perceive their infant to be in pain and may attribute excessive gas as a potential cause of the infant's distress. Rather, gas is likely a result of swallowed air caused by excessive crying and not the primary cause of the infant's symptoms.

The exact cause of colic remains elusive, and if colic is thought to represent the upper limits of

normal crying, it is possible that true pathology may not necessarily be present. A number of theories exist, including food allergy, gastrointestinal tract immaturity, parental stress, and infant temperament. Maternal smoking has also been implicated, and recent research suggests a possible association with migraine. Colic is a common concern in primary care practice, but exact estimates have been difficult to define. Prospective studies suggest a prevalence of between 3% and 28% of babies. These variable estimates likely reflect differences in study design and the population sampled.

### DIFFERENTIAL DIAGNOSIS

One of the most salient features of the infant with colic is that the child is an otherwise healthy baby. Because crying in the newborn can be a hallmark of a myriad of other disease processes, these must be excluded before a diagnosis of colic is made.

Some common disorders can be associated with excessive crying. The diagnosis of gastroesophageal reflux disease (GERD) may be suggested by episodes of fussiness. Fussy periods for the baby with GERD are often accompanied by emesis and typically occur soon after feeding. Milk protein intolerance can produce excessive crying but is often accompanied by diarrhea or hematochezia. Infants born to mothers who have used alcohol or other drugs during the pregnancy can be excessively fussy.

Other acute processes must be excluded. Such entities include corneal abrasion or hair tourniquet. Acute abdominal processes such as volvulus, intussusception, or an incarcerated hernia may produce irritability and constitute a medical emergency. Symptoms such as anorexia or vomiting may be present. Infectious processes such as otitis media, urinary tract infection, and meningitis are often accompanied by fever. Inflicted injuries such as fractures and intracranial bleeding must also be considered. These disorders typically exhibit persistent, rather than paroxysmal, symptoms.

### EVALUATION

#### History

A complete history is one of the physician's most important diagnostic tools in the evaluation of colic. The colicky baby is fussy, and parents may complain of excessive gas or crying and may be concerned that the infant is in pain. The physician must learn when these symptoms began, how often they occur, during what part of the day they occur, and how long they last. The chronicity and pattern of the symptoms is important. Parents can be asked what methods they have tried to reduce the symptoms and what, if anything, seems to help. The physician can use this opportunity to understand how the parent responds to the infant when the baby is in distress.

The physician should inquire about any concerns during the pregnancy, such as maternal drug use or infections. Family history includes a focus on metabolic or allergic disorders. Social factors are important. Parental anxiety regarding real or perceived health

concerns can affect their tolerance for normal infant crying. Understanding who in the family is responsible for caregiving and the types of supports available to the family is crucial.

The review of systems should be tailored to exclude signs and symptoms of organic illness such as fever, lethargy, vomiting, diarrhea, or hematochezia. A review of feeding techniques is important. For the formula-fed infant, care must be taken to ensure that the formula is mixed properly and that the baby is not being underfed or overfed. For breastfed infants, the physician should assess the mother's supply of milk and review how often and for how long the baby is fed.

### Physical Examination

The physical examination generally serves to exclude pathologic abnormalities and will in most cases be normal. The physician should perform a complete physical examination that focuses on the exclusion of organic causes of irritability. The infant will seem well, and parents may be frustrated that their overly fussy baby is quietly participating in the physical examination. This may serve as a teachable moment for physicians to highlight normal findings and the infant's overall health. Watching a physician conduct a thoughtful, thorough physical examination can help reassure parents that their concerns are taken seriously and that other diagnoses are not prematurely excluded. Abdominal processes, hair tourniquet around fingers or toes, and otitis media will be excluded by a thorough physical examination. Attention must be paid to adequate growth in weight, length, and head circumference, and these parameters should be plotted on the growth chart. Poor growth suggests inadequate nutrition or other organic causes. Increasing head circumference may raise concerns for hydrocephalus, including causes resulting from child abuse.

### Laboratory Evaluation

Laboratory testing is seldom indicated in the evaluation of colic. In most cases, the diagnosis can be made by a complete history and thorough physical examination. Laboratory testing is most often reserved for cases in which an organic cause is suspected. Unnecessary laboratory testing should be avoided unless clinically indicated because it may convey to parents the message that the baby is ill.

## MANAGEMENT

The management of colic primarily involves parental education and support. Foremost, the physician must help the parents understand that their baby is not sick and that the baby's excessive crying is not harmful. The baby's normal growth and physical examination can be used to help illustrate this point. Parents should be reassured about their abilities as caregivers and that they are not to blame for their baby's symptoms. Physicians should acknowledge the parents' frustration and let them know that the office will provide the family with support. Rather than informing the parents that colic may take months to resolve, physicians should remain positive and let parents know that some simple interventions will likely help alleviate the problem.

Parents can be encouraged to respond to their baby's fussiness with a predictable set of actions; having a plan to use during these fussy periods can be particularly reassuring. After first making sure that the baby is not hungry, soiled, or tired, parents can try to soothe the baby by encouraging non-nutritive sucking, swaddling, or gentle motions such as rocking or swinging. When crying continues despite these interventions, parents should be given permission to allow the infant to cry for a short period. This approach can allow parents to regroup and also provides the baby with some time to blow off steam. When conceptualized in these terms, parents may feel less anxious about the infant's continued crying. The pediatric office can provide families with support by offering a telephone contact in a few days to follow up on the infant's symptoms. Especially anxious parents can be offered an office visit within 1 week. Last, parents should be encouraged to take care of themselves, get adequate rest, and enlist family members or friends to take over from time to time to reduce caregiver stress.

Few medical interventions have proved helpful for colic. If indicated by history, a brief dietary change to a hypoallergenic formula or an elimination diet for breastfeeding mothers can be considered. Treatment for GERD can be instituted for infants with symptoms that suggest reflux. Pharmacologic therapies specific for colic have largely been found to be unhelpful and possibly harmful. Simethicone, a drug with few side effects, is not effective in symptom reduction. Dicyclomine, an anticholinergic drug, is effective; however, the manufacturer has advised against its use in children younger than 6 months because of case reports of adverse effects in infants. An herbal tea mixture of chamomile, vervain, licorice, fennel, and balm-mint has been shown to be effective, but the large volume of fluid (120 mL taken 3 times a day) might cause potential harm, such as hyponatremia or decreased milk intake. Recent studies using specific probiotic strains of *Lactobacillus reuteri* have shown promising results, although more studies are needed before probiotics can be universally recommended.

The prognosis for babies with colic is reassuring. For most babies, the symptoms of colic decrease dramatically by 4 months of age. Parents may be encouraged to know that the presence of colic in an infant does not necessarily predict a more difficult temperament as an older baby. Despite this favorable prognosis, care must be taken to support parents until they feel more comfortable managing their child's symptoms. Excessive parental anxiety and frustration may lead to later parent-child interaction problems, such as prolonged night waking, overfeeding, or the vulnerable child syndrome.

Education on infant crying and support for parents is important for caregivers of all newborns: in the hospital setting, at newborn visits, and at well child care appointments. Many parents are surprised to learn how much *healthy* babies cry, and excessive crying has been implicated as a stimulus for shaken baby syndrome. Prevention programs have been developed to promote positive coping techniques for infant

crying and to educate parents on the dangers of infant shaking. These programs include the Period of PURPLE Crying program, which uses the mnemonic PURPLE to remind parents of the characteristics of infant crying: P for the peak pattern, U for the unexpected timing of episodes, R for resistance to soothing, P for pain-like look, L for long bouts, and E for the evening cluster of symptoms. A similar program developed by Dias et al showed reduced rates of abusive head trauma when implemented in the community setting. Other support options for families include home visiting programs, such as the Nurse Family Partnership, which has shown decreased rates of child maltreatment when implemented in high-risk settings.

### WHEN TO REFER

Babies with colic seldom require a referral to a specialist. In rare cases, referral to specialists in developmental or behavioral pediatrics or mental health may be useful when parents are extremely anxious or in need of additional reassurance. Physicians should be alert for the parent who is overwhelmed by the infant's crying and in danger of harming the infant. In such a case, referral to children's services is necessary for the protection of the infant and support of the parent.

### WHEN TO ADMIT

In most cases, colic can be successfully managed in the outpatient setting. In rare situations when the history is confusing or suggests more serious symptoms, admission might be useful for observation to exclude other causes of irritability.

## Chapter 232

# COLORECTAL DISORDERS

Marc A. Levitt, MD; Jose M. Garza, MD; Alberto Pena, MD; Taiwo Lawal, MD

## HIRSCHSPRUNG DISEASE

### Introduction

Hirschsprung disease is characterized by partial or complete colonic obstruction associated with the absence of intramural ganglion cells. The aganglionic portion of the colon is always located distally, but the length of the segment varies. The most frequent variation (two-thirds of patients) is the one in which the aganglionic segment includes the rectum and much of the sigmoid colon (Figure 232-1). The long segment variety (10% of cases) has an aganglionic portion extending to any level between the hepatic flexure and the descending colon. Total colonic aganglionosis (10%) is a very serious condition in which the entire

**Figure 232-1** Hirschsprung disease affecting the rectum and much of the sigmoid colon.

colon is aganglionic, frequently including a variable length of terminal ileum.

The aganglionic portion of the colon appears narrow when compared with the distended, proximal part and demonstrates the absence of intramural, submucosal, and intermuscular ganglion cells with increased size and prominence of nerve fibers (hypertrophy >40 microns) and an increase in the enzyme acetylcholinesterase. Between these 2 areas is the *transition zone*.

Hirschsprung disease is believed to be caused by a failure in the development of tissue derived from the neural crest, with an arrest in the craniocaudal migration of the neuroenteric ganglion cells from the neural crest into the upper gastrointestinal tract, down through the vagal fibers, and along the distal intestine. As a consequence, ganglion cells are missing from the Auerbach myenteric plexus (located between the circular and longitudinal layers of the bowel wall), Henle plexus (located in the deep submucosa), and Meissner plexus (in the superficial submucosa). Ganglia are the final common pathway for both sympathetic and parasympathetic influences; their absence may produce the uncoordinated contractions of the affected bowel, leading to partial or total colonic obstruction.

### Epidemiology

Hirschsprung disease occurs in about 1 in 5,000 births and is more common in whites. Males are more frequently affected, but the long segment manifestation is seen at least as often in females. Inheritance patterns seem to be multifactorial. Down syndrome is found in 5% of these infants. A deletion in the long arm of chromosome 10 has been found, which seems to overlap the region of the *RET* proto-oncogene. Patients with multiple endocrine neoplasia type IIA also have a deletion of this proto-oncogene.

### Clinical Manifestations

Infants suffering from Hirschsprung disease usually become symptomatic during the first 24 to 48 hours of life. Occasionally, a child may have minimal or absent clinical manifestations during the first days or weeks and exhibit moderate, intermittent bouts of symptoms at a later age.

Abdominal distention, delayed passage of meconium, and vomiting represent the most frequent symptoms and may be followed by a spontaneous or induced explosive passage of liquid bowel movement and gas, which dramatically improves the baby's condition. This is followed by a period of hours or days of relative absence of symptoms followed by recurrence of the same manifestations. Stools are frequently liquid and foul. When the abdomen is distended, the infant can be very ill from sepsis, hypovolemia, and endotoxic shock. Volume loss is the result of diarrhea or intraluminal accumulation of fluid.

### Differential Diagnosis

The differential diagnosis includes any condition that causes distal intestinal obstruction in the newborn. Meconium plug syndrome, meconium ileus, small left colon syndrome, and other nonsurgical conditions such as hypothyroidism, adrenal insufficiency, opiate

intoxication, and cerebral injury can present with abdominal distention.

For late presenters, the diagnosis may be confused with chronic constipation. In the latter condition, children usually become symptomatic after the sixth month of life; they do not vomit or become seriously ill. A very important characteristic in this group of patients is overflow incontinence or encopresis—a constant, chronic soiling. Rectal examination reveals a severe fecal impaction just above the anal canal. Patients with Hirschsprung disease may have an empty rectum, or examination may disclose only a small amount of feces, and they often have chronic distention, failure to thrive, and episodes of enterocolitis.

### Diagnosis

#### Radiologic Studies

It is very difficult to differentiate distended colon from small bowel on a plain abdominal film of a neonate with intestinal obstruction. Therefore, one can only suspect the diagnosis of Hirschsprung disease from this study. The presence of air-fluid levels is evidence of obstruction, but it is nonspecific.

A water-soluble contrast enema examination (barium should be avoided) is the most valuable radiologic study for establishing the diagnosis. This study may reveal the presence of a distended proximal colon, the transition zone, and a “contracted” distal rectosigmoid (Figure 232-2). The older the patient, the more

**Figure 232-2** Water-soluble contrast enema examination showing distended proximal colon, transition zone, and “contracted” rectosigmoid.

obvious the size difference between the normal ganglionic intestine and the abnormal aganglionic bowel. The typical changes are not very obvious during the neonatal period, but usually the transition zone is recognizable. In instances of total colonic aganglionosis, contrast enema may reveal a short colon, with retraction of the hepatic and splenic flexures and straightening of the sigmoid.

### **Rectal Biopsy**

Confirmation of Hirschsprung disease requires finding the absence of ganglion cells and the presence of hypertrophic nerves in an adequate rectal biopsy. The specimen must be taken at least 1 cm above the pectinate line because closer to the dentate is always aganglionic. Suction biopsy is easily performed, is associated with virtually no risk for perforation, and does not require an anesthetic. The specimen usually measures 1 × 3 mm and should include mucosa and submucosa. A full-thickness biopsy done under anesthesia is required when the suction biopsy is nondiagnostic and in older children.

### **Medical Treatment**

Bowel irrigation with saline solution is an extremely valuable procedure for the emergency management of distention and vomiting. Decompressing the bowel in this way may dramatically improve a very ill infant.

It is extremely important to clarify the difference between an irrigation and an enema. To confuse these terms may be dangerous for babies with Hirschsprung disease. An enema is a procedure in which a determined amount of fluid is instilled into the rectum and colon with the expectation that this volume will be spontaneously expelled. A rectal irrigation, on the other hand, is a procedure in which a large tube is introduced through the rectum and small amounts of saline solution are instilled through the lumen of the tube to cleanse the bowel. The rectal and colonic content is expected to drain through the lumen of the tube. The tube is then rotated in different directions and moved back and forth. The operator continues to instill small amounts of saline solution, allowing the evacuation of gas and liquid stool through the tube.

Patients with Hirschsprung disease suffer from a very serious dysmotility disorder. An enema may aggravate the condition of the patient rather than help because the patient does not have the capacity to expel the infused volume of fluid. With an irrigation, the patient benefits from the evacuation of the recto-sigmoid contents through the lumen of the large tube, which overcomes the functional obstruction of the aperistaltic bowel, interfering with stasis and thus the ensuing bacterial overgrowth. This technique is vital to treat distention and enterocolitis before definitive surgery as well as after surgery if an episode of enterocolitis occurs.

### **Surgical Treatment**

#### **General Principles**

The ideal management of patients with Hirschsprung disease is to perform a primary procedure during the

neonatal period without a protective colostomy. The circumstances for performing the surgery are different from country to country, and there is often much variability in the experience of surgeons. In addition, the availability of experienced clinical pathologists may be limited. When performing a primary neonatal pull-through procedure, the surgeon must rely on frozen section analysis. For this, the surgeon must interact with an experienced pathologist who is familiar with the histologic diagnosis of Hirschsprung disease. A very ill newborn with enterocolitis or one who suffers from concomitant serious medical conditions may benefit from an initial fecal diversion. Similarly, a patient suffering from enterocolitis and unresponsive to irrigation may need a temporary diversion. With good neonatal care, effective irrigations, and experienced pathologists, this is rarely needed.

### **Definitive Operations**

In all surgical approaches, the goal is to resect the aganglionic segment and transition zone, pull through normal bowel, and preserve the continence mechanism.

#### **Swenson Procedure**

The Swenson procedure was initially done transabdominally, but it now can be done transanally. Laparoscopy has emerged as an excellent technique added to each type of Hirschsprung pull-through. Resection of the full-thickness aganglionic portion of the colon is performed, including that of the most dilated portion of the bowel (Figure 232-3). In most cases, the sigmoid readily reaches the perineum. Sometimes, mobilization of the splenic flexure is needed, which is easily done with laparoscopy. The long segment type may necessitate mobilization of the right colon to obtain sufficient length.

#### **Duhamel Procedure**

The Duhamel procedure was devised to avoid the pelvic dissection required of the Swenson operation. This is accomplished by preserving the aganglionic rectum and dividing the bowel at the peritoneal reflection as distally as possible. The rectal stump is then closed. Normal (ie, ganglionic) intestine, usually above the most dilated portion, is pulled through a presacral space that has been created by blunt dissection. The posterior rectal wall is incised above the dentate line, entering the previously dissected retrorectal space. The new, normally innervated colon is pulled through the rectal incision, and a stapler is used to effect anastomosis to the aganglionic rectum. The anastomosis between the colon and the aganglionic rectum must be created as wide as possible, and the rectal stump must be as small as possible to avoid fecal accumulation.

#### **Soave Procedure**

The Soave procedure removes the aganglionic recto-sigmoid by an endorectal dissection, which is begun 1 or 2 cm above the peritoneal reflection, theoretically minimizing the risk for pelvic injury associated with the Swenson procedure. The normally innervated colon is passed through a perirectal muscular cuff.

**Figure 232-3** Transanal approach to the management of Hirschsprung disease.

### Transanal Approach

In 1998, de la Torre and Langer both reported a transanal approach to the management of Hirschsprung disease. The basic concept consisted of approaching the resection of the aganglionic portion through the anus. A special retractor is ideal for this dissection (Figure 232-3). The circumferential traction exposes and protects the anal canal, the pectinate line, and the rectal mucosa. Multiple fine sutures are placed in the rectal mucosa in a circumferential manner to exert uniform traction and to facilitate the dissection of this part of the bowel. A circumferential incision distal to the multiple silk sutures is performed, and the dissection of the rectum commences and continues to the peritoneal reflection. As the dissection progresses, full-thickness biopsies are taken that are sent to pathology looking for the presence of ganglion cells as well as the thickness of the nerve trunks. The transition zone sometimes shows an area of hypoganglionosis and thickened nerves. The dissection continues until one goes above the transition zone to be sure that normoganglionic bowel is pulled down. The normoganglionic bowel is transanally anastomosed to the anal canal 1 cm above the pectinate line.

Considering that most patients with Hirschsprung disease have a transition zone in the sigmoid colon, it is possible to repair the entire defect using only the transanal approach without a laparotomy or laparoscopy. However, when the transition zone is located higher, laparoscopy or laparotomy is needed to mobilize the colon. An alternative is to commence the procedure laparoscopically, performing a colonic biopsy to identify the transition zone, mobilizing the sigmoid colon laparoscopically, and then dissecting transanally.

It is important to keep in mind that the resection must include not only the aganglionic part but also the dilated part of the bowel (Figure 232-3). Pulling down a very dilated segment of colon will result in severe constipation later in life because dilated bowel tends to lose its peristaltic ability.

### Post-Pull-Through Problems

After a technically sound pull-through, some patients may have difficulties with stooling for a few weeks after the operation. Post-pull-through enterocolitis is reported in 5% to 42% of patients; the wide variation is because of difference of opinion on what constitutes mild enterocolitis. The pathophysiologic mechanisms underlying the occurrence of enterocolitis after surgery are not completely known, but most patients do well when managed with rectal irrigation and metronidazole. Similarly, senna-based laxatives are beneficial in patients who are constipated. It is important to prevent a cycle of constipation provoking megacolon, which in turn produces more severe constipation.

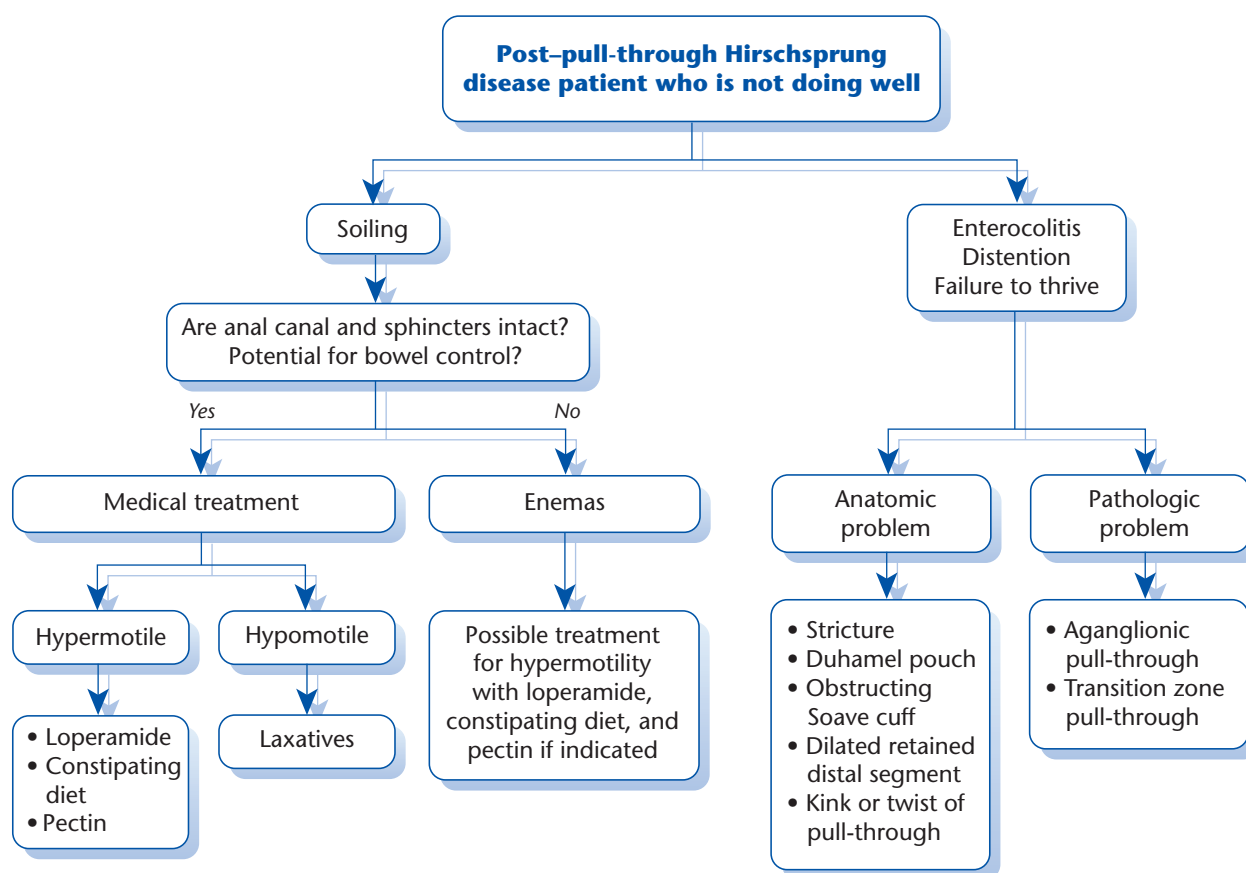

However, in a child with recurrent enterocolitis, persistent constipation or impaction, failure to thrive, and fecal incontinence, further evaluation is warranted. Patients with recurrent enterocolitis or constipation may have mechanical problems such as strictures, megarectal pouches, obstructing cuffs, or dilated segments. These could also be caused by retained aganglionic segments or a transition zone pull-through. Patients with fecal incontinence may have a lost or injured anal canal or sphincter mechanism. An algorithm (Figure 232-4) to evaluate and treat the patient is beneficial.

### WHEN TO REFER

- Features of enterocolitis
- Chronic abdominal distention
- As soon as the diagnosis is made
- Recurrent enterocolitis or failure to thrive after the pull-through
- Soiling after the pull-through

### WHEN TO ADMIT

- Enterocolitis unresponsive to irrigation and metronidazole

**Figure 232-4** Algorithm for the management of the patient with Hirschsprung disease who is not doing well after a pull-through.

## ANORECTAL MALFORMATIONS

### Incidence

About 1 of every 5,000 newborns will have an anorectal malformation (ARM). Males seem to suffer from this condition more frequently than females. The most common type of malformation seen in boys is rectourethral fistula, and the most common type of anomaly in girls is a rectovestibular fistula. There is an increased incidence of imperforate anus in children with Down syndrome, frequently consisting of a low-lying rectal pouch without a genitourinary or perineal fistula.

### Classification

Anorectal malformations include a spectrum of anomalies. Thus, in attempting to separate these groups of defects into categories, one risks being arbitrary and artificial. The anatomic classification shown in Box 232-1 is very useful for therapeutic purposes.

### Anatomy

The posterior sagittal approach used for the repair of ARM permitted the conceptualization of the anatomic details of a male (Figure 232-5) and a female (Figure 232-6) with ARM. The sphincter complex is

### BOX 232-1 Classification of Anorectal Malformations

#### MALE

- Rectoperineal fistula
- Rectourethral bulbar fistula
- Rectourethral prostatic fistula
- Rectobladder neck fistula
- Imperforate anus without fistula
- Rectal atresia/rectal stenosis

#### FEMALE

- Rectoperineal fistula
- Rectovestibular fistula
- Rectovaginal fistula (extremely rare)
- Cloaca
- Imperforate anus without fistula
- Rectal atresia/rectal stenosis

#### COMPLEX MALFORMATIONS

**Figure 232-5** Spectrum of male defects. (A) Perineal fistula. (B) Bulbar urethral fistula. (C) Prostatic urethral fistula. (D) Bladder neck fistula.

represented by a group of muscles that form a funnel-shaped continuum. The surgeon must find the distal rectum, mobilize it, and place it within the sphincter mechanism.

### Anorectal Malformations in Males

#### Perineal Fistula

Perineal fistula is the lowest malformation (Figure 232-5). In this malformation, the rectum has passed normally through much of the sphincter mechanism, but the distal part of the rectum is anteriorly deviated and ends as a perineal fistula anterior to the center of the sphincter mechanism. Frequently, the fistula tract lies immediately below a very thin layer of skin, with the external opening somewhere in the midline from the anus to the ventral portion of the penis. One often perceives beneath the midline skin a black or white ribbon-like structure due to meconium or mucus. The infant with this defect can undergo an anoplasty without a colostomy. Prognosis is excellent because the patient has all the necessary anatomic elements for maintaining bowel control.

#### Anal Stenosis and Rectal Atresia

Anal stenosis and rectal atresia are defects that consist of a ring of fibrous tissue located at the anal verge. The

anal canal is normal. The fibrous ring causes a stricture, but the muscle structure and the anal canal are completely normal. A Hegar dilator or thermometer is introduced to detect the malformation. The typical symptom is difficulty moving the bowels; the parent describes a ribbon-like appearance to the feces. This defect is particularly associated with a presacral mass, usually a teratoma.

#### Rectourethral Fistula

Rectourethral fistula is the most frequent malformation seen in males. The rectum descends through a considerable portion of the funnel-shaped muscle structure, but at some point, it deviates anteriorly and connects with the urethra. The most frequent site of the fistula is the bulbar urethra (Figure 232-5). A significant number of urethral fistulas open at the prostatic urethra (Figure 232-6). The quality of muscle in an infant with a rectourethral fistula is usually good. Higher malformations are more frequently associated with a poor sacrum and consequently poor innervation and deficient sphincter muscle. These newborns require a colostomy at birth followed by a posterior sagittal anorectoplasty (PSARP) performed in the first few months of life.

**Figure 232-6** Spectrum of female defects. (A) Perineal fistula. (B) Vestibular fistula. (C) Cloaca.

### **Rectal-Bladder Neck Fistula**

In the case of a rectal–bladder neck fistula, the rectum opens at the level of the bladder neck (Figure 232-5). The sphincter complex is frequently underdeveloped. The frequency of association with an abnormal sacrum, “flat bottom,” and urologic problems is very high. These infants must be treated with a colostomy at birth followed by a PSARP with a laparotomy or laparoscopy. This group represents about 10% of males. Ninety percent of infants with this anomaly have other defects. The ultimate functional result is poor.

### **Imperforate Anus Without Fistula**

Imperforate anus without fistula is a rare anomaly, occurring in 5% of all children with ARM, half of whom suffer from Down syndrome. More than 90% of the patients with Down syndrome who have an ARM have this specific defect. Despite the fact that these children have the trisomy 21 anomaly, 80% will have voluntary bowel control later in life.

The rectum usually ends blindly about 2 cm above the perineal skin. Even without a fistula, only a very thin membrane separates the rectum from the urethra. These infants usually have good muscle quality and a well-developed sacrum. Treatment consists of a colostomy in the newborn period followed by a PSARP at several months of life.

## **Anorectal Malformations in Females**

### **Perineal Fistula**

Perineal fistula is the most benign defect on the female spectrum. As with the male abnormality, the rectum

traverses most of the sphincter mechanism, deviating in its most distal portion to communicate with the skin through a fistula located a few millimeters anterior to the center of the sphincter mechanism (Figure 232-6). These infants have all the necessary elements for bowel control. An anoplasty (ie, minimal PSARP) is sufficient to treat this type of malformation without the need for a colostomy.

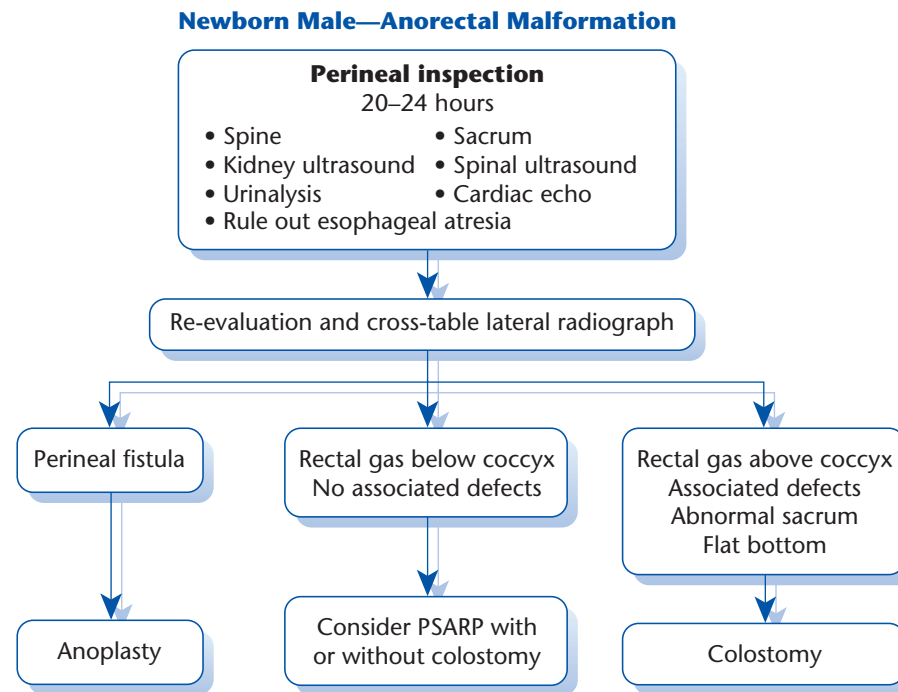

### **Vestibular Fistula**

Vestibular fistula is the malformation most frequently seen in females. The bowel is anteriorly deviated at a higher level, opening immediately behind the hymen into the vestibule (Figure 232-6). The rectum and the vagina have only a very thin, common wall separating them. The quality of sphincter muscle is usually excellent. Most patients have the potential for normal continence, a normal-appearing sacrum, adequate innervation, and a normal-looking perineum. There are exceptions in which one can find a vestibular fistula associated with rather inadequate muscle and a poor sacrum.

This malformation is frequently misdiagnosed as a *rectovaginal fistula*. A true vaginal fistula is extremely rare. Meticulous examination of the genitalia of a newborn is required to precisely localize the fistula site and make an accurate anatomic diagnosis.

An infant born with this defect, with no associated anomalies, who is otherwise well, can be operated on within the first 48 hours without a colostomy. However, one must be mindful that a protective colostomy is still a very valuable adjunct under several circumstances.

**Figure 232-7** Algorithm for the management of a newborn male with an anorectal malformation. PSARP, posterior sagittal anorectoplasty.

The most common one is the lack of experience in the performance of the definitive repair. Also, a baby with an associated defect or in very poor clinical condition may be optimally managed with a colostomy.

This particular malformation is the one that is unfortunately most frequently managed incorrectly. Even when these children have a high likelihood of bowel control, a failed procedure will often jeopardize that potential. A simple cut-back procedure, which does not include separating the vagina from the rectum, will almost always require a secondary repair as a consequence of incontinence and inadequacy of the perineal body.

#### **Imperforate Anus Without Fistula**

Imperforate anus without fistula is an uncommon malformation in females. The rectum is usually located about 2 cm above the skin. There is a good sphincter muscle, a good-looking perineum, and a well-developed sacrum. Half of these female babies, like the males, have Down syndrome. The surgeon can approach the patient posterosagittally and without a colostomy during the newborn period. The creation of a colostomy is still a reasonable alternative when the clinical circumstances are not ideal.

#### **Anal Stenosis and Rectal Atresia**

Anal stenosis and rectal atresia are treated in the same manner in females and males. Again, the surgeon must look for a presacral mass.

#### **Persistent Cloaca**

Persistent cloaca represents the extreme in the spectrum of complexity of female malformations. With this

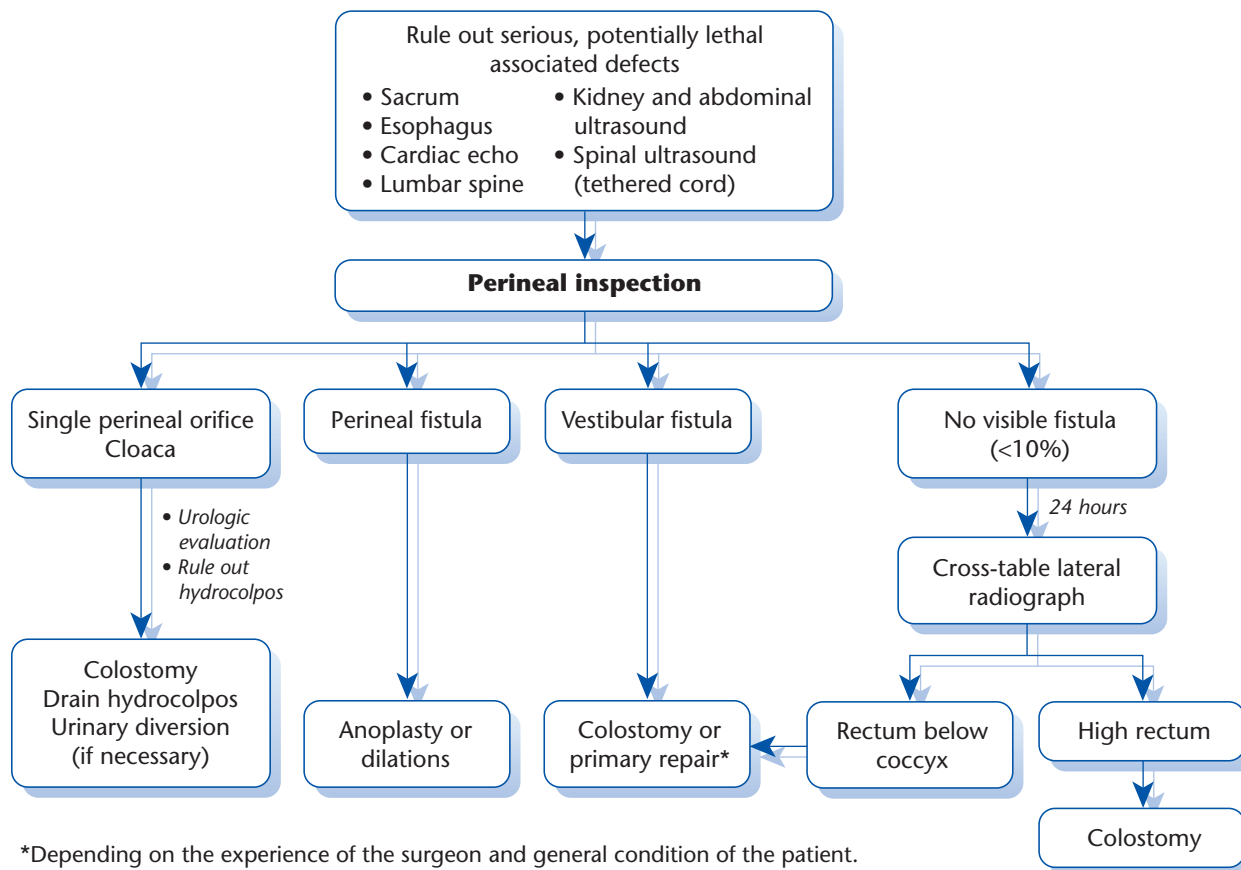

anomaly, the rectum, vagina, and urinary tract meet and fuse together into a single channel (Figure 232-6). Meticulous examination discloses a single orifice at the urethral site with no evidence of vagina or rectum.

Persistent cloaca is represented by a spectrum of defects. Many infants have a double or septated vagina, with different degrees of septation or division of the uterus. Frequently, the vaginal opening into the cloaca does not drain and thus collects urine, with a resultant hydrocolpos. The length of the common channel varies from 1 to 7 cm, which affects how challenging the repair will be. Lower, short cloacae, with good sphincter muscles and sacrum, are easier to repair; longer cloacae are frequently associated with poor muscles and inadequate sacrum, have poor potential for continence, and are a significant technical challenge to repair, often requiring complex maneuvers including vaginal replacement.

In managing this malformation, one is committed to achieving bowel control, urinary continence, menstruation, sexual function, and childbearing potential for the patient. These malformations are frequently associated with urologic concerns. In the newborn period, patients must have a colostomy, sometimes need a vaginostomy for decompression of a hydrocolpos, and occasionally require urinary diversion. At an appropriate interval, these procedures are followed by a definitive reconstruction, a posterior sagittal anorectovaginourethroplasty.

#### **Management in Males**

Figure 232-7 and Figure 232-8 illustrate an algorithmic approach to decision making in the management of newborn infants (male and female) with ARM.

**Newborn Female: Anorectal Malformation**

\*Depending on the experience of the surgeon and general condition of the patient.

**Figure 232-8** Algorithm for the management of a newborn female with an anorectal malformation.

Simple perineal inspection and a urinalysis in about 90% of cases will allow one to determine whether the patient needs a colostomy. It takes a significant amount of intraluminal bowel pressure to overcome the muscle tone of the sphincter mechanism to allow the meconium or the gas to reach the most distal part of the bowel and be forced through a tiny fistula orifice. This explains why diagnostic studies aimed at determining the height of the malformation and the location of the fistula, when performed before 16 to 24 hours of life, lead to an erroneous diagnosis of a “high” ARM. During the initial hours of life, potentially lethal conditions, mainly cardiac, esophageal, and urologic, must be ruled out. The baby should receive intravenous fluids and antibiotics and receive no oral food or fluids, with a nasogastric tube to avoid vomiting and aspiration. Abdominal ultrasound, spinal ultrasound, radiography of the lumbar and sacral spine, and an echocardiogram are performed. After 24 hours of observation, with a good index of suspicion and a perineal inspection, the surgeon will have enough information to determine whether the baby needs a colostomy or a primary repair. For a minority of patients (10%), a cross-table lateral film with the baby in prone position is needed; this will show the presence of gas in the most distal rectum and can help the

surgeon to determine whether to approach the baby with or without a colostomy.

### Management in Females

Determination of the need for a colostomy is an easier decision in female infants because in 95% of cases the bowel opening in the perineum is evident. Decisions concerning colostomy or primary repair should not be made before 24 hours of life. The first hours of life should be used to evaluate for hydrocolpos, hydronephrosis, a cardiac malformation, esophageal atresia, tethered cord, or other spinal defects. The presence of a cutaneous fistula (Figure 232-6) is evidence of a very low malformation, which can be treated with a minimal PSARP without a colostomy.

The presence of a vestibular fistula (Figure 232-6) can be an indication for a colostomy or primary approach, depending on the specific surrounding circumstances. If the surgeon has experience with the primary approach and the baby is full term and has no significant associated malformations, the operation can be done primarily within the first few days of life. If the baby is sick for other reasons or has significant associated defects, or if the surgeon does not have the necessary experience, it is better to open a colostomy and to postpone the main repair until a later date. Dilatation of the fistula with delayed reconstruction is also an option.

If the baby has a single perineal orifice, the diagnosis of a cloaca is established (Figure 232-6). The infant requires a full urologic evaluation and evaluation for a hydrocolpos. A colostomy is indicated, and it is mandatory to drain the hydrocolpos, if present, during the same operation. Occasionally, babies with a cloaca have a near atresia of the urethra and therefore need a vesicostomy.

If the baby does not have a visible fistula, which happens in about 5% of cases, a cross-table lateral radiograph with the baby in prone position can show rectal gas below the coccyx, and depending on the surgeon's experience, the patient can be approached primarily or posterosagittally; if the gas is located much higher than the coccyx, it is advisable to open a colostomy.

### Prognosis

Individuals born with an absent or poorly developed sacrum have poor potential for fecal and urinary continence. Infants with a normal sacrum and good sphincter muscle structures usually attain fecal and urinary control. PSARP permits reconstruction of these defects by placing the rectum in the optimal position to achieve the best functional results. However, many patients continue to have bowel management problems, primarily because of anal canal sensory impairment, sphincter deficiency, and motility disturbance. These can contribute to varying degrees of soiling and constipation.

In one series, voluntary bowel movements were noted in 75% of patients. When separated by diagnosis, the percentages varied: 100% in patients with rectal atresia and perineal fistulas, 95% in those with vestibular fistula, 80% in those with rectourethral bulbar fistula, 70% in those with cloacae, 65% in those with rectourethral-prostatic fistula, and 15% in patients with bladder neck fistula. Despite the fact that patients may have voluntary bowel movements, about 50% of them occasionally soil their underwear, particularly if the stools are loose. Constipation was a problem in 40% of all children and was more frequently noted in those with lower defects. Urinary incontinence was present in about 5% of males and females (excluding cloacal reconstructions). In those with cloacae, urinary incontinence was found in 20% of females who had a common channel shorter than 3 cm and in 80% of those who had longer common channels, but this can be managed with intermittent catheterization. Definitive conclusions about sexual function, menses, and obstetric potential require longer follow-up. Patients with fecal incontinence can be kept clean artificially with a bowel management program, which consists of a tailored daily enema.

### WHEN TO REFER

- As soon as diagnosis is made (prenatal or at birth)
- In a child with repaired ARM, with soiling at the age of potty training

### WHEN TO ADMIT

- A single perineal opening in a female
- Male newborn with a rectourinary fistula
- Major associated anomalies
- When there is abdominal distention, regardless of the presence of fistula

## RECTAL PROLAPSE

### Introduction

Rectal prolapse is a relatively common problem in children. It is usually seen before the age of 4 years, with a peak incidence in the first year of life, probably related to the relatively vertical configuration of the sacrum, a sigmoid colon that is very mobile, and rectal mucosa that is loosely attached to the underlying muscularis. Rectal prolapse ranges in severity from involvement of only a small ring of mucosa to involvement of all rectal layers. The mildest form, mucosal prolapse, is the most common form seen in children. The mucosa prolapses intermittently during defecation or crying and reduces spontaneously. It is particularly problematic when the child has severe constipation. The prolapse may progress to full thickness, which can only be reduced manually. The most severe form occurs when the prolapse cannot be reduced manually, which leads to venous congestion, vascular compromise, and ulceration.

### Causes

Rectal prolapse is usually idiopathic, but there may be an underlying cause that must be sought. Malnutrition, a common predisposing factor in the developing world, produces a depletion of the perirectal cushion and its supportive role for the pelvic diaphragm. Improvement of the nutritional status usually leads to resolution of prolapse.

Parental anxiety with premature attempts at toilet training and constipation is implicated in many cases of idiopathic rectal prolapse. Straining during defecation, spending long sessions on the toilet, protracted diarrhea, and chronic constipation allow stretching of the pelvic diaphragm and result in prolapse. Increased intra-abdominal pressure caused by straining during coughing spells, especially with lung diseases and straining during urination, are also known to produce prolapse in children.

Cystic fibrosis is present in up to 25% of cases of rectal prolapse in children. This prolapse is often recurrent and related to poor nutrition, poor muscle tone, increased intra-abdominal pressure due to the pulmonary component of the disease, and passage of large volumes of stool. Patients with neurologic disorders affecting the innervations of the pelvic floor, such as myelomeningoceles, often have paralysis of the levators and, with raised intra-abdominal pressure, are predisposed to having full-thickness rectal prolapse.

Rectal prolapse occurs in 3% of children who have had surgery for ARM. The severity of the prolapse after PSARP is related to the type of malformation. A higher malformation is indicative of more severe caudal regression and therefore weaker pelvic sphincter

muscles and nerves and a higher likelihood of rectal prolapse.

### Clinical Features

The parents usually make the diagnosis in most mild cases of rectal prolapse. They report a dark red, fleshy mass protruding from the anus following complaints of discomfort at the anus by the child while defecating. This may be seen along with mucus or blood but is usually painless. The prolapse may reduce spontaneously or after manual efforts by the child or parents. In most cases, the prolapse is absent between defecation and is not present when the child is examined. The history is geared toward identifying a predisposing factor.

A useful maneuver is to ask the child, if old enough to cooperate, to squat and see whether the prolapse can be identified. Digital rectal examination findings are usually normal. Differentiation between a mucosal and a full-thickness prolapse can be done by feeling the mass between the thumb and middle finger of the examining hand. The prolapse, if present, should be reduced gently and the rectum examined for the presence of an occasional polyp, which may be the predisposing factor. A patulous anus with a gaping anal canal may signify an underlying problem with pelvic innervation.

With a full-thickness prolapse that has been difficult to reduce manually, the child may present with pain and copious mucous discharge associated with the mass. Bluish discoloration is suggestive of venous congestion, and if the mass has been present for a long time, there may be areas of hyperemia and ulceration. It may be difficult to reduce in the clinic given the amount of edema, which can be helped by sprinkling sugar on the edematous area.

### Differential Diagnosis

It is important to differentiate rectal prolapse from a prolapsing intussusception of the sigmoid colon. The examining finger, in intussusception, feels a deep sulcus around the circumference of the mass such that the apex cannot be reached by the finger from below. This is unlike rectal prolapse, in which the finger runs in a continuous fashion over the mass and onto the rectal mucosa. It is sometimes impossible to clinically differentiate these 2 and an abdominal ultrasound or contrast enema is necessary.

Another differential diagnosis is a prolapsing rectal polyp occurring in the absence of a rectal prolapse. The polyp may appear during defecation or episodes of straining, and it reduces spontaneously.

### Management

Most cases of idiopathic rectal prolapse can be managed conservatively, which involves reduction of the prolapse, identification and treatment of predisposing factors, and prevention of constipation and straining. The prolapse, if present in the examining room, should be reduced. This can be done by grasping the mass between the fingers and pushing it gently back into the anus. In the presence of edema, reduction can be achieved by maintaining a gentle but firm and

steady pressure on the mass. Sprinkling sugar on the protruded mucosa helps eliminate some of the edema. In some instances, the mass may prolapse after reduction. Reduction should be repeated, and the buttocks may then be strapped together with adhesive tapes for a few hours to prevent repeat prolapsing. If the prolapse is recurrent, the parents can be taught how to effect a gentle reduction at home while the patient is being investigated for an underlying cause. Constipation usually can be managed appropriately once the primary condition is resolved. Laxatives may be beneficial in patients with chronic constipation.

Some changes to the toilet training technique may be beneficial. Having the child use a child-specific “potty” rather than an adult commode and prevention of prolonged sitting on the toilet are helpful to reduce the recurrence of the prolapse.

If there is recurrence despite conservative measures, a sigmoidoscopy to evaluate for the presence of rectal polyps should be performed.

Numerous options have been employed for surgical treatment after failure of a conservative approach. Injection sclerotherapy has a success rate of 75% to 90% and may need to be repeated or combined with other modalities to achieve better results. Complications include perirectal inflammation, ischiorectal abscess, urinary retention, and necrosis of the rectal mucosa. Perianal cerclage with Silastic bands or nonabsorbable sutures (Thiersch procedure) tightens the anal canal and prevents prolapse while allowing for the integrity of the perianal musculature to be restored. The success rate has been reported at more than 90%; complications include breakage of the cerclage and anal erosion. Open posterior rectopexy involves fixation of the rectum to the sacrum. Laparoscopic rectopexy involves suturing of the rectum to the periosteum of the sacral promontory. Other surgical techniques include cauterization therapy, mesh rectopexy, anterior sling rectopexy, rectosigmoid resection, mucosal stripping, and a transanal approach to resect the prolapse and perform an anoplasty similar to a Hirschsprung type of operation. The surgery is done under direct visualization, with protection of the dentate line and avoidance of fecal incontinence.

### Prognosis

Most patients (90%) with rectal prolapse between the ages of 9 months and 3 years are successfully managed conservatively. The prognosis, in terms of resolution of the prolapse, is poorer in children who develop prolapse after the age of 4 years. These children are likely to have neurologic or pelvic floor disorders.

#### WHEN TO REFER

- Irreducible prolapse
- Failure of conservative measures and having excluded a predisposing cause

#### WHEN TO ADMIT

- Irreducible prolapse

## Chapter 233 COMMON COLD

Howard Fischer, MD

Colds are viral infections of the upper respiratory tract, and the mucosal surfaces that are lined with respiratory epithelium are involved. Thus, nasal passages, sinuses, eustachian tubes, middle ear spaces, conjunctivae, and the nasopharynx are potentially affected. The distribution of this illness is worldwide, and adults and children of all ethnic groups are susceptible. Colds are most common in preschool children, who average 6 to 8 colds per year, a number that is about 4 times the number expected in adults. Children who attend child care centers or who are exposed to other school-aged children tend to have more colds

than children who spend most of their time at home. Frequent infection in the preschool years might lower the frequency of colds in the school years.

## EPIDEMIOLOGIC FEATURES

Colds have always tended to occur more frequently during the cooler months in temperate climates, probably leading to the popular myth that exposure to cold weather leads to a cold. Fortunately, the common cold has been researched extensively in the past few decades, allowing primary care physicians to have a more scientific understanding of this illness. In fact, in the northern hemisphere, the incidence of colds peaks in early fall, remains high during the winter, and decreases in the spring. Studies have shown that exposure to a cold environment neither causes a cold nor decreases immunity that may potentially allow a viral infection to begin. Clearly, however, colds are more frequent in crowded situations, and evidence suggests that the infection begins most commonly after self-inoculation of a virus onto the individual's own nasal or conjunctival mucosa.

Because the viruses of infected individuals are shed in large numbers in nasal secretions, they can be spread easily by way of fingers and hands to objects such as clothing and environmental surfaces, where fingers of other children can acquire them and then self-inoculate their respiratory tracts by picking their noses or rubbing their eyes. Inhalation of virus-containing aerosols is also an effective means of virus acquisition. Studies in adult populations have shown that colds are more likely to develop after inoculation by rhinovirus in persons who are under chronic stress; whether this likelihood is the case in children is not known.

## ETIOLOGY

More than 100 different infectious agents can cause cold symptoms, with rhinoviruses and small RNA viruses of the picornavirus family implicated most frequently. In addition to many rhinovirus serotypes, other viruses and a few nonviral organisms are associated with the common cold (Table 233-1). Although respiratory syncytial virus and parainfluenza viruses most commonly cause a croupy cough and bronchiolitis in infants, they may cause a cold in older children and adults. Adenoviruses and enteroviruses tend to cause other

**Table 233-1** Causative Agents of Colds

AGENT	RELATIVE IMPORTANCE	PEAK SEASON
Rhinovirus	Most frequent cause	Autumn
Coronavirus	Frequent cause	Winter
Influenza virus	Less frequent cause	Winter
Respiratory syncytial virus	Less frequent cause	Winter
Parainfluenza virus	Less frequent cause	Autumn and spring
Enterovirus	Occasional cause	All seasons
<i>Mycoplasma pneumoniae</i>	Occasional cause	All seasons
Metapneumovirus	Unknown	Autumn and winter

Human metapneumovirus infection in the United States: clinical manifestations associated with a newly emerging respiratory infection in children. *Pediatrics*. 2003;111:1407–1410.

symptoms in addition to those of a common cold, including pharyngitis and gastrointestinal problems.

### **PATHOPHYSIOLOGIC FEATURES**

When a cold-causing virus is introduced into the host's respiratory tract, assuming no immunity exists to the particular serotype, a local infection usually begins after an incubation period, the length of which depends on the specific virus. However, not all people who have a viral respiratory tract infection (defined as evidence of viral shedding and an increase in antibody titers) develop symptoms of a cold. In one study, only 75% of experimentally infected adults who shed rhinovirus type 2 and developed a greater than 4-fold rise in antibody titers actually developed symptoms. The symptoms of a cold are related primarily to the host's production of interleukin-8 and other vasoactive peptides in response to the viral infection, resulting in increased vascular permeability and mucus hypersecretion.

### **CLINICAL PRESENTATION**

Infants may begin their illnesses with fever; an older child, however, is usually afebrile, with a stuffy nose and watery nasal discharge, followed in a few days by sneezing. Generalized symptoms such as headache, malaise, and myalgia are uncommon with a rhinovirus infection, although they are seen in adenoviral and other viral infections. Infants tend to be irritable, have changes in feeding and sleep patterns, and sometimes develop mild diarrhea. By the third or fourth day of the illness, a dry cough may be present, and the nasal discharge usually becomes more purulent. Although such purulence has been interpreted in the past as indicating a secondary bacterial infection (eg, sinusitis), little evidence is available to support this impression. Of adults who had colds and sinus abnormalities on computed tomography scan, only 2% developed bacterial sinusitis. Furthermore, examination of purulent secretions has not shown increased aerobic bacterial growth or sloughing of nasal epithelial cells, and biopsies in volunteers demonstrate only loss of cilia and ciliated cells. Although viral sinusitis is a common finding during a cold, progression to bacterial sinusitis is probably quite rare in children.

Generally, the symptoms of a cold last about 1 week; however, a child may occasionally have mild rhinorrhea and a dry cough for 2 to 3 weeks. The cilia necessary for proper function of the respiratory epithelium may take as long as 3 weeks to return to their normal state, thus delaying the return to a symptom-free condition.

### **DIFFERENTIAL DIAGNOSIS**

Persistent nasal symptoms can also be caused by allergy. For allergies to be diagnosed initially as colds and later recognized as seasonal or associated with nasal eosinophilia is not uncommon. Cold symptoms associated with significant pharyngitis, rashes, or other systemic symptoms are usually caused by viruses other than those causing the common cold. Streptococcal pharyngitis is not usually associated with rhinorrhea or cough.

Occasionally, a persistent purulent nasal discharge in children younger than 2 years results from a  $\beta$ -hemolytic

streptococcal infection, although this condition is usually associated with mild excoriations around the nares. Unilateral nasal discharge must also be evaluated carefully to rule out a nasal foreign body. Finally, irritation and swelling of the nasal passages from inhalation of drugs such as cocaine or the chronic use of medicated nasal sprays should be considered in the older child who has persistent cold symptoms. The possibility of infection with *Bordetella pertussis* should be considered in a child with persistent cough. Children who have been partially immunized may not have a characteristic whoop associated with *B pertussis* infection.

## **MANAGEMENT**

### **Laboratory Procedures**

No routine tests exist to diagnose the common cold. Viral cultures are expensive and generally unnecessary; thus, the diagnosis should be made on clinical grounds. The most common concern is that an underlying bacterial infection (eg, sinusitis, acute otitis media) is missed or treated improperly. If a cold follows its expected course of causing usual symptoms for 5 to 7 days, then a concurrent bacterial infection is unlikely. When the symptoms of a cold are prolonged, a secondary infection may be present, especially if fever persists or is prominent or if ear pain or a productive cough develops. Thus, ear and lung examinations are essential for a child whose cold has persisted longer than expected. The routine use of radiographs or computed tomography scans to diagnose sinusitis is not necessary because when studied (albeit in older individuals), the radiologic finding of opacification of the sinuses has not correlated with the clinical indications of sinusitis.

### **Treatment**

The various remedies available for the common cold provide—at best—symptomatic rather than curative treatment. In children, most of the remedies give only marginal symptomatic relief, if any; in many cases, they are potentially quite harmful. Over-the-counter cough and cold medications should not be used in children younger than 2 years because serious and potentially life-threatening side effects can occur from their use. Furthermore, studies have shown that these medications are generally ineffective in children younger than 6 years. Most pediatricians, at most, suggest saline nose drops with the use of a bulb syringe to aspirate secretions and a cool-mist vaporizer to humidify room air. The malaise and fever sometimes associated with a cold can be treated with acetaminophen or ibuprofen; aspirin should be avoided in children because of its association with Reye syndrome. Some studies suggest that ibuprofen may be more beneficial during a cold than acetaminophen because it leads to a shorter period of viral shedding and a better neutralizing antibody response.

Studies conducted on preschoolers have not demonstrated a beneficial effect of decongestants or antihistamines, singly or in combination. In older children and adolescents, an oral decongestant such as pseudoephedrine hydrochloride, either alone or

with an antihistamine (probably owing to antihistamine's anticholinergic effect), provides symptomatic relief with a low possibility of side effects. The use of nasal spray or drops containing vasoconstrictors such as oxymetazoline hydrochloride should be discouraged because of the high incidence of rebound nasal congestion after only a few days of use. Although studies in adults indicate some decrease in symptoms when steroid or atropine-like nasal sprays are used, their use in children has not been evaluated. The use of mast cell stabilizers, such as nedocromil and sodium cromoglycate given intranasally or by inhalation, has shown some promise in adult studies. Their place in pediatric care is not clear.

The use of zinc lozenges to reduce the duration of cold symptoms has been studied extensively in adults in recent years with conflicting results. Despite at least 8 placebo-controlled trials and several reviews of these studies, the efficacy of zinc lozenges remains controversial. Studies of potential antirhinoviral drugs are still too preliminary to judge their therapeutic potential. Many parents will ask about the advisability of giving vitamin C during a cold, and many will request that the physician prescribe antibiotics. Vitamin C use has not been proved efficacious. Discouraging antibiotic use is particularly important when bacterial infection is unlikely, given current evidence of the increasing drug resistance among some bacterial pathogens.

Because of the lack of effective treatment for the common cold, parents may turn to alternative treatments. A commonly used cold treatment is an extract of the plant *Echinacea*. A recent randomized clinical trial showed no benefit to the use of extract of *Echinacea purpurea* in treating children 2 to 11 years of age at the onset of their colds. Similarly, a randomized clinical trial in adults using *E angustifolia* extract showed no benefit in treating experimental rhinovirus infection.

## COMPLICATIONS

Most colds are self-limited and resolve without the help of the physician or of any medication. When a fever arises 3 to 4 days after cold symptoms begin or symptoms continue longer than expected, a complication such as otitis media or pneumonia should be suspected. A cold can apparently contribute to eustachian tube dysfunction, especially in younger children, resulting in acute otitis media. A fever, headache, and unilateral purulent nasal discharge may herald a secondary bacterial sinusitis, although this condition is probably diagnosed more frequently than it occurs. On rare occasions, a lower respiratory tract infection develops and may progress to pneumonia, characterized by cough, tachypnea, and usually fever. The pneumonia may have a viral origin or may be caused by a secondary bacterial infection. Chest radiograph can confirm the diagnosis.

The role of rhinovirus infection as a trigger of exacerbation of reactive airway disease has now been well documented; thus, the development of wheezing or a prolonged cough after a cold should alert the physician to this possibility.

## Chapter 234

# CONGENITAL AND ACQUIRED HEART DISEASE

Michael A. McCulloch, MD; Robert J. Gajarski, MD, MHSA

The initial evaluation, continued care, and timing for referral of children with congenital and acquired heart disease are aided by a basic understanding of cardiac embryology, genetics, anatomy, and physiology.

## EMBRYOLOGY

Understanding fetal cardiac embryology allows insight into possible sources of error and how these imperfections can lead to clinically significant congenital heart diseases (CHDs).

The primitive heart starts as a linear tube that begins pulsating in a coordinated fashion to produce forward flow at approximately 17 days postconception and becomes the first functioning organ in the developing embryo. Small invaginations separate the primitive heart into 5 distinct regions. From caudal to cranial, they are the sinus venosus, primitive atrium, primitive ventricle, bulbus cordis (conus), and truncus arteriosus. These segments ultimately form the cardiac chambers and some of the extracardiac blood vessels.

At approximately 20 to 23 days postconception, the primitive heart segments demonstrate differential rates of growth, resulting in curving or looping of the heart on itself (Figure 234-1). As a result, the sinus venosus and primitive atrium are positioned dorsal and cranial to the primitive ventricle, whereas the bulbus cordis and truncus arteriosus are slightly ventral and cranial. At this stage of development, the individual cardiac segments have experienced very little differentiation. The primitive atrium is a single chamber receiving all blood from the sinus venosus. This blood is then propelled forward into the primitive ventricle, bulbus cordis, truncus arteriosus, and the rest of the developing embryo (Figure 234-2).

**Figure 234-1** Depiction of the embryologic heart tube undergoing normal, rightward looping. The primitive atrium and sinus venosus ultimately change their location from posterior and caudal to dorsal and cephalad. (From Moore KL, Persaud TVN. *The cardiovascular system*. **Figure 234-2** Rightward looped embryologic heart sectioned along its sagittal plane. The arrows depict the normal course of blood flow at 20 to 23 days postconception. (From Moore KL, Persaud TVN. *The cardiovascular system*. In: Moore KL, Persaud TVN, eds. *The Developing Human: Clinically Oriented Embryology*. 5th ed. Philadelphia, PA: WB Saunders; 1993, with permission. Copyright © 1993, Elsevier.)

In the beginning of the fourth week, the atrioventricular valves begin to form. Two collections of cells, called endocardial cushions, proliferate from the ventral and dorsal surfaces of the primitive heart at the junction of the primitive atrium and primitive ventricle. These endocardial cushions grow toward each other and ultimately fuse. Concurrent with this formation is the development of walls, or septa, which ultimately separate the primitive atrium into right and left atria, the primitive ventricle into the left ventricle, and the bulbus cordis into the right ventricle (Figure 234-3). The crux of the heart is formed when the atrial and ventricular septa attach to the fused endocardial cushions, transforming the linear heart tube into 4 distinct chambers.

While the atrioventricular valves and cardiac septa are being formed, the truncus arteriosus is simultaneously dividing into the primitive aorta and pulmonary

**Figure 234-3** Rightward looped embryologic heart sectioned along its coronal plane. Illustration demonstrates fusion of the endocardial cushions and the resulting sites of the future mitral and tricuspid atrioventricular valves. At this stage of development, postconception days 22 to 25, the developing embryologic heart has double-inlet left-ventricle and double-outlet right-ventricle morphology. (From Moore KL, Persaud TVN. *The cardiovascular system*. In: Moore KL, Persaud TVN, eds. *The Developing Human: Clinically Oriented Embryology*. 5th ed. Philadelphia, PA: WB Saunders; 1993, with permission. Copyright © 1993, Elsevier.)

artery (Figure 234-4). The aortopulmonary septum is formed when 2 ingrowths of tissue develop and proliferate toward one another. When they meet in the midline, the truncus arteriosus is divided approximately in half. The caudal end of this septum will ultimately fuse with the region of endocardial cushion and atrioventricular septal connection (Figure 234-5).

Before fusion of the endocardial cushions and aortopulmonary and atrioventricular septa, all the blood flow from the left and right atria returns directly to the primitive ventricle (future left ventricle), through the bulbo-ventricular foramen to the bulbous cordis (future right ventricle), and ultimately to the truncus arteriosus. The truncus arteriosus then provides blood to the developing pulmonary arteries and aorta. Therefore, at this stage in development, the heart is functionally a double-inlet left ventricle and a double-outlet right ventricle.

The progression from a double-inlet left ventricle and double-outlet right ventricle heart to a 4-chambered heart with separate great arteries to the body and lungs is understandably complex. This process involves migration of the developing atrioventricular valves, with their respective atria, and the truncus arteriosus, with its developing great arteries, toward one another. This relocation of the major heart structures results in the atria and great arteries being positioned directly over their respective ventricles. Final cardiac anatomic form is achieved by approximately 8 weeks postconceptional age and only increases in size until birth.

## GENETICS OF CONGENITAL HEART DISEASE

CHD is the most common birth defect in the United States, with an incidence of 8.1 to as high as 50 per 1,000 live births, depending on inclusion criteria. As a

**Figure 234-5** Final stages of cardiac development demonstrated in the coronal plane, removing the ventral portion of the developing right ventricle and pulmonary artery. Both the atrioventricular canal and great arteries have been formed. The superior portion of the IVS and the inferior portion of the aortopulmonary septum will meet at the region of the fused endocardial cushions. Once this step is completed, the embryologic heart will be separated into 4 distinct chambers and function as a mature heart. (From Moore KL, Persaud TVN. *The cardiovascular system*. In: Moore KL, Persaud TVN, eds. *The Developing Human: Clinically Oriented Embryology*. 5th ed. Philadelphia, PA: WB Saunders; 1993, with permission. Copyright © 1993, Elsevier.)

**Figure 234-4** Division of the truncus arteriosus into the pulmonary artery and aorta. The aortopulmonary septum is formed by 2 opposing ingrowths of tissue and results in a spiraling of the forming great arteries around one another. (From Moore KL, Persaud TVN. *The cardiovascular system*. In: Moore KL, Persaud TVN, eds. *The Developing Human: Clinically Oriented Embryology*. 5th ed. Philadelphia, PA: WB Saunders; 1993, with permission. Copyright © 1993, Elsevier.)

growing number of these patients survive to have children of their own, understanding the genetic basis of their heart defect becomes increasingly important. However, this endeavor is significantly complicated by CHD's genetic heterogeneity, because different gene mutations cause similar heart defects and single gene mutations can produce a variety of different heart defects. The fetal environment further influences gene expression. Therefore, although autosomal-dominant inheritance can exist with multiple syndromes (eg, DiGeorge, Williams, Alagille, Noonan, Holt-Oram), even these recognizable phenotypes are commonly caused by sporadic mutations. A large cross-sectional study of 1.7 million Danish citizens demonstrated only 2.2% of CHD patients had affected first-degree relatives, supporting a larger role for spontaneous or recessive genetic mutations whose expression may be accentuated by in utero exposures.

Conversely, many well-recognized genetic syndromes are associated with specific CHDs. Approximately 50% of trisomy 21 patients have CHD, with atrioventricular canal defects present in 45%. Children with Turner syndrome commonly have abnormalities of the aortic valve and aortic arch with some form of CHD occurring in 21%. Aneuploidy of chromosomes 18 and 13 are almost universally associated with hemodynamically significant ventricular or atrial septal defects and valvular disease. Noonan syndrome (pulmonary stenosis, hypertrophic cardiomyopathy), 22q11 deletion/DiGeorge syndrome (left ventricular outflow tract obstruction, aortic arch anomalies), Alagille syndrome (peripheral pulmonary stenosis) and many other common syndromes have a relatively predictable CHD profile.

Although chromosomal abnormalities were historically documented in only 8% to 13% of all neonates with CHD, the advent of fluorescence in situ hybridization (FISH) and other testing modalities has significantly increased the incidence of documented gene malformations in these patients. Such information could prove invaluable by identifying other possible organ system involvement, long-term prognostic information, commensurate reproductive risks for children and their family, and determining whether other family members should also undergo genetic testing. For these reasons, some institutions obtain genetics consultations for all patients newly diagnosed with CHD.

## CONGENITAL DEFECTS

### Intracardiac Shunting Lesions

Shunting lesions are heart defects in which a proportion of the blood volume from one side of the heart is added to the blood volume on the other side. Shunting can be from the left side of the heart to the right, the right side of the heart to the left, or bidirectional. The right heart is composed of the systemic veins (inferior vena cava [IVC] and superior vena cava [SVC]), an atrium, a ventricle, and a great artery; generally, these structures are the right atrium, right ventricle, and pulmonary artery, respectively. Conversely, the left heart is composed of the pulmonary veins, an atrium, a ventricle, and a great artery; generally, these

structures are the left atrium, left ventricle, and aorta, respectively.

### Physiology

The process of *adding* or shunting blood from one side of the heart to the other is regulated by a few basic principles of physics. First, blood flows from the higher resistance circuit into a lower resistance circuit. In a normal heart, left-sided resistance are considerably higher than those on the right, and, if given the opportunity, blood will preferentially shunt from left to right. The volume of shunted blood also depends on the size of the defect through which it flows. A very large defect will allow considerably more flow to shunt from the left heart to the right than a small defect. However, even if the defect is large, if the resistance difference is minimal (as with pulmonary hypertension), the volume of shunted blood will be small.

Different components of the cardiovascular system will respond uniquely to volume or pressure loading. Atria and ventricles will gradually dilate to accommodate excess blood volume (preload) being added to their respective chambers. If faced with excess pressure (or afterload), then the ventricular myofibers will hypertrophy not only to generate the required driving pressure, but also to minimize myocardial wall stress for maximal pump efficiency. The pulmonary arterioles can also hypertrophy when subjected to prolonged periods of high pressure. However, although cardiac dilatation and hypertrophy are generally reversible, the pulmonary arteriolar hypertrophy associated with longstanding pulmonary hypertension often is not and can result in increased pulmonary vascular resistance (PVR) and fixed, deadly pulmonary hypertension.

### Clinical Manifestations

A cardiac murmur is audible blood flow through the heart or vascular system. A murmur can be auscultated in a normal heart resulting from hyperdynamic function or a thin chest wall. Generally, a diastolic murmur is not normal. A systolic murmur may be normal (functional) or it may be pathologic. Regardless of the timing, location, or cause of the murmur, its frequency and pitch depend on the size of the opening through which the blood flows and on the pressure gradient across it.

### Left-to-Right Shunting Lesions

#### Ventricular Septal Defect

One of the most common types of CHD is the ventricular septal defect (VSD). Nearly 20% of patients in heart disease registries have a solitary VSD. This defect, or hole, in the septum separating the 2 ventricles allows blood to traverse from one side of the heart to the other. Left-sided heart pressure generally exceeds that on the right side. Therefore, blood will preferentially shunt from left to right. Given that most VSDs are positioned in the membranous septum near the aortic and pulmonary valves, the volume of shunted blood is not *seen* by the right ventricle and is instead added directly to the pulmonary

circulation. In the case of large VSDs, this addition of blood results in left-ventricle volume overload. Over time, the left heart will dilate to accommodate this increased volume. This dilatation is likely mediated by fiber realignment in response to the volume load, which causes increased wall stress. Increased muscle mass, or myocyte hypertrophy, occurs to normalize this wall stress. However, the abnormal mechanical stresses that are inherent in the chronically volume-loaded, dilated ventricle can ultimately result in myocyte dysfunction and heart failure. In contrast, although a small VSD will still result in left-to-right shunting, the smaller defect will allow a proportionately smaller volume of shunted blood that may never be hemodynamically significant.

### **Atrial Septal Defect**

Another differential lesion with left-to-right shunting is the atrial septal defect (ASD). Similar to the VSD, the volume of shunted blood depends on the size of the defect. In contrast to the VSD, however, shunting across an ASD is dependent on a difference in atrial compliances, not a difference in resistances. A difference in chamber compliance is the dominant force directing blood from left to right. The highly compliant right atrium becomes a sink for blood draining into the smaller, less compliant left atrium by the pulmonary veins. This additional blood volume is then routed into the right ventricle, resulting in right-heart dilatation over time.

### **Clinical Manifestations of Atrial Septal Defect and Ventricular Septal Defect**

Despite increasing sensitivity of fetal echocardiography, smaller ASDs and VSDs may not be detected prenatally. Instead, they are usually detected by the presence of a murmur, with or without the signs of heart failure. The timing of their presentation depends on the size of the defect and whether the infant has fully transitioned from fetal circulation.

Right- and left-sided resistances are nearly equivalent shortly after birth and do not produce a substantial pressure gradient for the shunting of blood. During the transition to postnatal circulation, as the PVR falls, the left-right gradient increases along with the volume of oxygen-rich blood shunted to the right heart. A small VSD with a high pressure gradient between the 2 ventricles will produce a high-pitched, holosystolic murmur that continues from the onset of ventricular systole through the closure of the atrioventricular valves (obscuring the first heart sound) to the closure of the semilunar valves. A large VSD may not produce a murmur because the interventricular pressure gradient will be minimal. The VSD murmur will be loudest at the left lower sternal border and may be best described as a mid-frequency blowing murmur. Auscultation of an ASD will differ significantly from that of a VSD. The lack of a marked pressure gradient between the 2 atria does not produce a murmur at the site of shunting. Rather, the murmur of an ASD is caused by excess volume traversing the pulmonary valve, commonly described as a “relative” pulmonary stenosis. It is described as a mid-frequency systolic ejection murmur best auscultated at the left sternal

border and will commonly radiate to the lung fields bilaterally.

By definition, left-to-right shunting results in pulmonary overcirculation. However, the symptoms of pulmonary edema typically do not develop until the pulmonary artery blood flow has doubled in volume. A neonate with a large VSD may demonstrate poor weight gain and lethargy as PVR decreases, increasing the gradient for shunting from the left ventricle to the right; if untreated, then heart failure (marked pulmonary overcirculation) may ensue. Conversely, the relatively smaller volume of blood shunting across a comparably sized ASD will remain asymptomatic for many years. Regardless of the mechanism, the PVR will reflexively increase in proportion to the degree of shunt volume (in ASD and VSD) and pressure (in VSD) to reduce stress on the arteriolar walls. Over time, these pulmonary arterioles can become quite hypertrophied and unable to vasodilate. This irreversible state of pulmonary arteriolar vasoconstriction results in pulmonary hypertension.

### **Evaluation of Atrial Septal Defect and Ventricular Septal Defect**

**ELECTROCARDIOGRAM.** The electrocardiogram (ECG) can be normal for age in patients with both ASDs and VSDs. As chamber dilatation or hypertrophy occurs, however, signs of ventricular or atrial enlargement may develop (Figure 234-6). The classically described ECG finding for patients with ASDs is an RSR' in lead V1 from volume overload of the right ventricle. The ECG may also be helpful for identifying the onset of pulmonary hypertension by the gradual development of right-ventricular hypertrophy (Figure 234-7).

**CHEST RADIOGRAPH.** Chest radiography is generally noncontributory in diagnosing left-to-right shunt lesions before the onset of pulmonary overcirculation and the resulting pulmonary edema. Once pulmonary overcirculation has developed, however, the cardiac silhouette will gradually increase in area, and pulmonary vascular markings will become substantially more prominent. Chest radiography can also be used to help assess effectiveness of medical management such as diuretic therapy.

**ECHOCARDIOGRAM.** Any child with a known congenital heart defect should be primarily managed by a pediatric cardiologist along with his or her primary care pediatrician. When present, a 2-dimensional echocardiogram will show a defect in the interatrial or inter-ventricular septum and allow for determination of cardiac function (Figure 234-8). Doppler flow velocities across the defect can estimate pressure differences between the respective chambers. Together, this information can help guide timing and type of surgical correction, if indicated.

### **Management of Atrial Septal Defect and Ventricular Septal Defect**

Children with known septal defects should be monitored closely for weight gain, development, and clinical status. Any signs of respiratory distress or failure to thrive will generally occur during the first 6 months of

**Figure 234-6** ECG of a 3-year-old boy with a large ASD. Note the RSR' in lead V1 and mildly peaked P waves in leads V1 and II. These findings are consistent with right-ventricular and right-atrial dilatation, respectively.

**Figure 234-7** ECG of a 2-year-old child with a large VSD. Note the large voltages of both R and S waves in all of the precordial leads as well as right-axis deviation of the QRS axis. These findings are consistent with biventricular hypertrophy and elevated PVR caused by longstanding exposure of the pulmonary vasculature to left-sided blood pressures.

life and should prompt re-evaluation by the pediatric cardiologist. Although medical management (ie, diuretics, potentially afterload reduction) can temporarily improve these complications, definitive closure of either an ASD or VSD is indicated when signs of pulmonary overcirculation develop.

#### **Prognosis of Atrial Septal Defect and Ventricular Septal Defect**

Small ASDs and VSDs can close spontaneously. Small defects in the muscular portion of the interventricular septum (IVS) are often closed by the trabeculated muscle growth of the right ventricle; VSDs in other regions of the IVS may also close, but this is relatively less common. Researchers have suggested that the natural history of secundum-type ASDs is largely

dependent on the initial defect size, with nearly 85% of those less than 5 mm in diameter closing spontaneously versus less than 2% when the defect is more than 8 mm in diameter. Children with moderate or large VSDs that do not close spontaneously or are not associated with pulmonary overcirculation are at risk for developing the serious complication of pulmonary vascular obstructive disease (PVOD). The normal, physiologic decline of PVR after birth is altered when the lungs are subjected to excess volume from left-to-right shunting. In some children, the PVR never decreases after birth or decreases at a slower rate and then increases. These children will have few or no symptoms of pulmonary overcirculation. As a result, they may not be brought to a physician's attention. Persistently elevated PVR, especially if associated with

**Figure 234-8** Apical 4-chamber echocardiographic view of a 4-month-old infant with a large VSD (*short arrow*). Note the dilated left ventricle and the relationship of the defect to the aortic valve (*long arrow*).

hypoxemia, is a potent stimulus for intimal and medial thickening of the pulmonary arterioles. Elevated PVR produces elevated pulmonary artery pressures and eventually pulmonary hypertension (mean pulmonary pressures exceed 25 mm Hg at rest). If unrepaired, children with this physiologic situation will have persistently elevated PVR that can eventually become irreversible. This state can occur as early as 6 months of age, particularly in children with trisomy 21 (Down syndrome) and as early as 1 year in children without Down syndrome. When pulmonary artery pressures exceed those of the left ventricle, the direction of shunted blood will become right to left, producing central cyanosis (Eisenmenger syndrome). Therefore surgical correction of these defects must be accomplished in a timely fashion.

Surgical mortality rates are reported as less than 1% for both ASDs and VSDs. Alternatively, device closure of ASDs in the cardiac catheterization laboratory is becoming more common. A recent study comparing device closure of ASD with surgical correction demonstrated a failure rate requiring surgical repair in 4% of device patients but a complication rate of only 7.2% compared with 24% in the surgical group. Device closure of VSDs is currently being performed in limited situations. Success rates have been reported to be 99% but have been associated with a nearly 50% serious complication rate. Ongoing cardiology care is recommended throughout childhood and adolescence to monitor for intermediate-term or late sequelae, including development of subpulmonic stenosis or aortic insufficiency (after VSD closure) or atrial tachyarrhythmias (particularly after late ASD closure).

## Other Common Left-to-Right Shunting Lesions

### Patent Ductus Arteriosus

When the ductus arteriosus does not involute shortly after birth, it is a potential source of shunting from the aorta to the pulmonary arteries once PVR decreases. A patent ductus arteriosus (PDA) is most commonly encountered in premature infants and can be associated with worsening chronic lung disease, poor renal perfusion, hemodynamic instability, intraventricular hemorrhage, and necrotizing enterocolitis. If the usual treatment with indomethacin is contraindicated or unsuccessful, then the PDA can often be surgically ligated. If persistent into childhood and a source of symptomatic left-to-right shunt, then surgical ligation or catheter-based coil embolization (in appropriately selected candidates) can be performed.

### Atrioventricular Septal Defects

Nearly 50% of all children with trisomy 21 have CHD; nearly 50% of these are atrioventricular septal defects (AVSDs; also known as atrioventricular canal defects or endocardial cushion defects). Approximately 70% of all children with AVSD have trisomy 21. This defect describes a continuum of malformations from a partial type (primum type ASD with a cleft mitral valve) to a complete type (single atrioventricular valve spanning the entire width of the heart; Figure 234-9, A) with variability in the attachment of the atrioventricular valve leaflets to the IVS. These defects can result in a significant left-to-right shunt volume. Timing of the surgical repair for complete AVSD follows the same principles for the simple VSD described previously and is generally performed between 3 and 6 months of age to minimize the potential for irreversible pulmonary hypertension. A partial AVSD follows ASD physiologic characteristics and can generally be repaired up to a few years of age with a low risk of developing irreversible pulmonary hypertension. The ECG of children with the complete defect generally demonstrates a northwest, superior QRS axis and some element of ventricular hypertrophy (Figure 234-9, B).

Surgical repair of a complete AVSD includes patch closure of the ASD and VSD and the creation of 2 functioning atrioventricular valves from the single, frequently regurgitant common atrioventricular valve. Postoperative outcomes depend on the severity of any residual atrioventricular valve regurgitation and the presence of pulmonary vascular disease. With detection of a change in the systolic regurgitant murmur or presence of a new harsh systolic ejection murmur during routine general care, the primary care physician can assist the cardiologist in monitoring for progression of any residual postoperative mitral regurgitation or development of new subaortic outflow tract obstruction, respectively, which are possible sequelae following AVSD repair.

### Arteriovenous Malformation

Arteriovenous malformation (AVM) is a direct connection between the arterial and venous vascular systems resulting in shunting of blood to the right heart

**Figure 234-9** A, Apical 4-chamber echocardiographic view of a 3-month-old infant with Down syndrome and a complete AVSD. Note the large ASDs and VSDs (top and bottom arrows, respectively) and the dilatation of both atria and ventricles. The double arrow points to the common atrioventricular valve spanning both ventricular chambers. B, ECG of the same patient demonstrating a northwest QRS axis (QRS forces are predominantly negative in leads I and aVF) with a small Q wave in lead aVL; this finding is typical in patients with AVSDs. In addition, note the large voltages in the precordial leads and peaked P waves in leads II and aVF consistent with biventricular dilatation and right atrial enlargement, respectively.

and possible high-output, right/left-sided heart failure. Common AVM locations in children are cerebral and abdominal. If amenable to interventional occlusion, coil embolization may reduce or reverse heart failure in many cases.

### Right-to-Left Shunting Lesions

Systemic, central cyanosis is the key difference between left-to-right and right-to-left shunting lesions. By definition, a right-to-left shunting lesion is one in which oxygen-poor blood is being shunted or added to the oxygen-rich, systemic blood. As with left-to-right shunting lesions, the volume of shunted blood depends on the size of the defect and the pressure gradient across it.

### Tetralogy of Fallot

Tetralogy of Fallot is one of the most commonly encountered cyanotic heart defects, occurring in 0.33 per 1,000 live births and comprising approximately 7% of heart defects. Although its embryologic origin remains controversial, one of the prevailing theories asserts that this defect occurs as a result of disproportionate segregation of the truncus arteriosus into the pulmonary artery and aorta. This uneven distribution results in malalignment of the aortopulmonary septum with the developing IVS creating a VSD, which then underlies both the aortic and pulmonic valves. This anatomic arrangement, coupled with the stenotic pulmonary valve and concomitantly narrowed right-ventricular outflow tract (RVOT), results in right-to-left shunting of right-ventricular blood through the VSD into the aorta, producing systemic, central cyanosis. Not surprisingly, the volume of shunted blood can vary with alteration of the pressure gradient through the RVOT. The proverbial *Tet spell*, or hypercyanotic event, occurs when systemic vascular resistance (SVR) decreases, resulting in an increased right-to-left shunt. Some researchers have suggested that muscle contractions or spasms in the RVOT

increase the obstruction to pulmonary flow and thereby worsen cyanosis. Regardless of the cause, treatment for a hypercyanotic spell is the same. Supplemental oxygen, fluid boluses, anxiolytics, sedatives, and increased SVR (ie, knee-to-chest positioning, phenylephrine) work to decrease the amount of right-to-left shunting. If not reversed, hypercyanotic spells can be fatal.

### Eisenmenger Syndrome

Although less common in the current era, another potential cause for right-to-left shunting occurs in the setting of unrepaired VSDs or large ASDs with secondary pulmonary hypertension and is known as Eisenmenger syndrome. Significant shunting and progressive cyanosis with this physiologic phenomenon will only occur once the pulmonary vascular resistance is higher than the systemic vascular resistance. In addition to the complications of systemic cyanosis and the compensatory rise in hematocrit, patients with pulmonary hypertension are at a significantly elevated risk for right-ventricular failure and sudden death.

### Pulmonary Hypertension

Pulmonary arterial hypertension (PHTN) is a progressive disease of the pulmonary vascular bed resulting in increased afterload and strain on the normally low-pressure right ventricle. Untreated, the median survival is less than 4 years, with death typically occurring from right-ventricular failure or ischemia-induced dysrhythmias. The last 2 decades of research, however, have significantly improved our understanding of PHTN's molecular pathology, and the associated advancement of currently available medical therapies has increased 10-year survival to nearly 80%.

Lung biopsies of patients with severe PHTN demonstrate a continuum of pathologic changes to the pulmonary arteriole. Dysfunction of the endothelial cells within the intima is commonly indicted as the sentinel event of this disease process with progressive loss of

the vasodilatory component of autoregulation. Such changes result in hypertrophy and hyperplasia of the medial smooth muscle layer, a concomitant decrease in luminal cross-sectional area, and increased pulmonary vascular tone. This level of disease typically remains amenable to medical therapy. Without intervention, however, the intimal layer will progressively occlude and the medial layer becomes fibrotic, resulting in fixed obstruction to affected regions. Medical therapies are designed to replete the vasodilatory pathways (nitric oxide, prostaglandin  $I_2$ ), inhibit the maladaptive vasoconstrictive agents (endothelin-1), and prevent platelet aggregation and thrombosis.

The diagnosis of a child with PHTN is often delayed by several years from the onset of symptoms, and is often not considered in the differential diagnosis until the nonspecific complaints of fatigue, decreased activity levels, episodic exercise-induced chest pain, or shortness of breath become associated with syncope, cyanosis, or aborted sudden death. These symptoms are secondary to progressive right-ventricular dysfunction with inadequate systemic cardiac output. Physical examination may be grossly normal, but more advanced disease can present with hepatomegaly, jugular venous distention, peripheral edema, a loud second heart sound, and the murmur of tricuspid regurgitation. An ECG will demonstrate right axis deviation with right-ventricular hypertrophy. The echocardiogram is used to initially rule out CHDs (see Eisenmenger syndrome). In a structurally normal heart with severe PHTN, the echocardiogram will demonstrate a dilated right heart with right-ventricular hypertrophy and pressure estimates (using tricuspid regurgitation jet, pulmonary insufficiency jet, or interventricular septal position) that are commonly classified as sub systemic, systemic, or suprasystemic. There is often a patent foramen ovale or atrial septal defect that allows blood to shunt from the right atrium to the left when right-ventricular pressures are acutely elevated. This atrial level ‘pop-off’ can result in systemic cyanosis, but in the setting of a pulmonary hypertensive crisis (acute, severe elevation of PVR reducing flow through the pulmonary vascular bed), it can allow for important filling of the left ventricle that it would not otherwise receive. Cardiac catheterization is used to confirm the diagnosis and provide hemodynamic data to help guide medical therapy. Extensive laboratory and imaging studies are also necessary to help differentiate primary (idiopathic) from secondary PHTN, which can develop from autoimmune, pro-coagulant, infectious, toxin-mediated, or pulmonary parenchymal processes.

Calcium channel blockers were historically the only available vasodilator for PHTN. However, their extensive side effect profile and poor long-term efficacy (less than 25% of pediatric patients will continue to respond after 12 months) have significantly limited their role in present-day medical regimens. Instead, oral sildenafil and bosentan have become first-line agents along with prostaglandin  $I_2$  analogues. Sildenafil is a phosphodiesterase-5 inhibitor which promotes vasodilation by accentuating the nitric oxide-mediated vasodilatory response in vascular smooth muscle,

**Table 234-1**

**Description of the  
6 Grades of Systolic or  
Diastolic Murmur Severity**

MURMUR SEVERITY	DESCRIPTION
Grade I	Barely audible and may require several cardiac cycles to detect
Grade II	Soft, but easily audible
Grade III	Moderately loud murmur without a thrill
Grade IV	Loud murmur with a thrill
Grade V	Loud murmur heard with the stethoscope barely off the chest
Grade VI	Loud murmur heard without the stethoscope touching the chest

while bosentan is a nonselective endothelin-1 receptor antagonist that inhibits vasoconstriction. Epoprostenol is a prostaglandin  $I_2$  analogue commonly viewed as the most potent extrinsic pulmonary vasodilator available to the physician and likely has survival advantages over the commonly used oral therapies, but is typically administered as a continuous intravenous infusion in children and carries a significant side effect profile.

### **Clinical Manifestations of Right-to-Left Shunting Lesions**

Tetralogy of Fallot is a defect commonly detected by prenatal ultrasound between 18 and 22 weeks' gestation. The clinical presentation can be extremely varied depending on the degree of pulmonary stenosis or the presence of pulmonary atresia (no prograde flow across the pulmonary valve).

In addition to cyanosis, newborns with tetralogy of Fallot will commonly demonstrate an audible murmur. A systolic murmur may be appreciated at the left upper sternal border and is produced by the narrowing of the RVOT. Its grade (I-VI/VI) and quality (harsh or soft) depends on the degree of obstruction (Table 234-1). In the newborn with tetralogy of Fallot and pulmonary atresia, the RVOT murmur is replaced by a continuous flow murmur through the ductus arteriosus, the only source of pulmonary blood flow.

With the exception of cyanosis and softer murmurs, the physical examination of a child with pulmonary hypertension caused by an untreated septal defect (Eisenmenger syndrome) may be virtually indistinguishable from that of a simple ASD or VSD. One other subtle difference may be a loud pulmonary valve (P2) component of the second heart sound. Idiopathic pulmonary hypertension (see previous section) or pulmonary hypertension secondary to bronchopulmonary dysplasia may demonstrate cyanosis (from intrapulmonary or right-left atrial level cardiac shunting), and a loud P2 may not have an associated cardiac murmur (in the absence of pulmonary or tricuspid insufficiency). Equal ventricular pressures in

**Figure 234-10** Chest radiograph of a newborn with tetralogy of Fallot demonstrating a *boot-shaped* heart. The *toe* of the boot is formed by the cardiac apex being lifted off the diaphragm from right-ventricular hypertrophy. Note the absent pulmonary artery knob expected to exist at the left sternal border between the fourth and sixth ribs.

a patient with Eisenmenger syndrome secondary to a VSD will not produce an audible murmur.

#### Evaluation of Right-to-Left Shunting Lesions

**ELECTROCARDIOGRAM.** Tetralogy of Fallot and pulmonary hypertension often produce evidence of right-ventricular hypertrophy. Right-axis deviation and tall R waves in the early or right-sided precordial leads can be seen on ECG.

**CHEST RADIOGRAPH.** Right-to-left shunting, by definition, is associated with decreased pulmonary blood flow. As a result, pulmonary vascular markings may be significantly decreased in children with either tetralogy of Fallot or secondary pulmonary hypertension. The classic radiographic finding of tetralogy of Fallot is the boot-shaped cardiac silhouette. This result is caused by the superiorly displaced cardiac apex produced by right-ventricular hypertrophy and absence or reduction of the pulmonary knob (Figure 234-10). The relative right-ventricular hypertrophy in the normal newborn often results in the erroneous reading of a boot-shaped cardiac silhouette on initial chest radiographic examination.

**ECHOCARDIOGRAM.** Two-dimensional and Doppler echocardiogram evaluations define cardiac anatomy, function, and direction of blood flow across any cardiac defects. Doppler flow velocity across the RVOT allows estimation of outflow gradient, degree of obstruction, and any evidence of branch pulmonary artery stenosis.

#### Management of Right-to-Left Shunting Lesions

**TETRALOGY OF FALLOT.** Surgical management of tetralogy of Fallot has changed significantly over the last two decades. The advent of microsurgical and novel bypass techniques has allowed for repair during infancy or the newborn period. For this reason, true

hypercyanotic episodes in toddlers are rarely observed in present day.

**TETRALOGY OF FALLOT WITHOUT PULMONARY ATRESIA.** Once diagnosed, children with tetralogy of Fallot without pulmonary atresia are generally monitored in the intensive care unit until their ductus arteriosus (if present) closes. If these children are able to produce enough pulmonary blood flow to maintain arterial oxygenation saturations ( $\text{SaO}_2$ ) greater than 80%, they may be discharged from the hospital and allowed to grow. The occurrence of a hypercyanotic spell (Tet spell) is generally considered a semi-urgent indication for repair. Otherwise, in the absence of earlier unacceptable cyanosis ( $\text{SaO}_2 < 75\%$ ), elective repair is performed when the child is 4 to 6 months old.

Operative correction consists of patch closing the VSD and removing obstruction to pulmonary blood flow through the narrowed RVOT. This can be accomplished through trans-atrial resection or division (or both) of RVOT muscle bundles, and, depending on the pulmonary valve and proximal artery anatomy, performing a pulmonary valvotomy or placing a trans-annular patch after valvectomy to relieve distal outflow obstruction (Figure 234-11). In many cases, since pulmonary valvectomy will be required as part of the repair, patients will be left with significant pulmonary insufficiency (PI). This will necessitate long-term, regular follow-up given that the progressive RV dilatation and eventual dysfunction associated with PI are long-term morbidities that will often require surgical or catheter-based pulmonary valve placement.

**TETRALOGY OF FALLOT WITH PULMONARY ATRESIA.** If tetralogy of Fallot is associated with pulmonary atresia, then a prostaglandin E1 infusion will maintain ductal patency until surgical repair. If pulmonary artery size is favorable (ie,  $> 3$  mm in diameter), then complete repair can be performed in the neonate; otherwise, an aortopulmonary shunt is placed to allow pulmonary artery growth until a complete repair is performed later. In the patient without confluent pulmonary arteries who relies instead on multiple aortopulmonary collaterals, the surgical options are more difficult. The collateral arteries can be unifocalized through a single or staged procedure to a patch-augmented native outflow tract or conduit arising from the right ventricle. The early and long-term results of this procedure have been promising with 10- and 20-year actuarial survival rates of 86% and 75%, respectively, and freedom from surgical reintervention rates of 55% and 29% at 10 and 20 years.

**EISENMENGER SYNDROME.** Management of patients with an unrepaired septal defect who have developed Eisenmenger syndrome poses a unique problem. Right-to-left shunting in this situation occurs to maintain adequate cardiac output at the expense of systemic oxygenation. Surgical closure of the septal defect will worsen the outcome if the pulmonary hypertension cannot be ameliorated first. Therefore, multiple approaches are used to decrease pulmonary artery pressure and ultimately the amount of right-to-left shunting. Calcium channel blockers, nitric

**Figure 234-11** Depiction of surgical repair for tetralogy of Fallot. In the setting of a hypoplastic pulmonary valve annulus, a patch of fixed bovine pericardium is sized to fit the vertical incision site, which starts in the main pulmonary artery and traverses the pulmonary valve into the right ventricle's infundibulum. The *transannular* patch placement is depicted in the middle drawing. The bottom right drawing depicts the surgical approach to repairing a patient with tetralogy of Fallot without a hypoplastic pulmonary valve. The main pulmonary artery incision is made to allow patch augmentation of the main pulmonary artery, and the incision in the right-ventricular infundibulum is made to permit patch augmentation of the RVOT. Not shown is repair of the VSD or muscle bundle resection, which is usually performed through the tricuspid valve.

oxide donors, endothelin receptor antagonists, inhaled oxygen therapy, and, in severe cases, continuous infusions of prostacyclin have all been found to improve symptoms in patients with pulmonary hypertension (see previous section on pulmonary hypertension). If the pulmonary vasculature proves to be reactive with these measures, surgical intervention may then be considered. When the pulmonary vasculature does not respond to these medications, lung transplantation (in acceptable candidates) or supportive, symptomatic care may be the only therapeutic options available.

### Other Right-to-Left Shunting Lesions

**PULMONARY ATRESIA WITH INTACT VENTRICULAR SEPTUM.** Researchers have proposed that membranous pulmonary atresia and intact ventricular septum with 2 adequately sized ventricles occurs late in embryologic development. This otherwise structurally normal heart develops complete fusion of the pulmonary valve preventing any forward flow into the pulmonary artery from the right ventricle. Blood entering the right ventricle is instead regurgitated through the tricuspid valve back into the right atrium

where it mixes with SVC and IVC blood. The increase in blood volume increases right atrial pressure, resulting in shunting of blood across the patent foramen ovale to the left atrium. This circuit does not change with transition from fetal circulation, and pulmonary blood flow becomes dependent on a persistent PDA. Once diagnosed, the pulmonary valve may be opened in the cardiac catheterization laboratory using balloon dilatation or radiofrequency ablation to perforate through the valve cusps. This latter approach is controversial, and, in many institutions, surgical valvotomy remains the preferred approach for valve atresia.

Another subset of patients develops pulmonary atresia much earlier in cardiac development. The subsequent lack of right-heart blood flow in utero results in hypoplasia of the right ventricle and tricuspid valve and, in some cases, can be associated with sinusoidal connections between the hypoplastic right ventricle and coronary arteries. When present, decompression of the right ventricle through a pulmonary valvotomy can result in myocardial ischemia, infarction, and death. If the right heart structures are significantly

affected, the patient must instead follow the single-ventricle treatment route (see later discussion of single-ventricle physiology). The surgical specifics of that single-ventricle palliation will be determined by the presence or absence of the sinusoids described previously.

**ISOLATED PULMONARY VALVE STENOSIS.** Isolated stenosis of the pulmonary valve is a relatively common CHD, affecting 3.8 of 10,000 live births. While similar from an embryologic and anatomic perspective, isolated pulmonary valve stenosis and pulmonary atresia with an intact ventricular septum are different in many ways. By definition, stenosis differs from atresia by the presence of prograde flow across the pulmonary valve. Although probably inaccurate, it is convenient to compare the 2 lesions by considering isolated pulmonary valve stenosis as an incomplete version of its more severely affected counterpart. Most importantly, however, is the lack of coronary sinusoidal formation or the right-ventricular dependent coronary artery flow often accompanying the more severe forms of pulmonary atresia with intact ventricular septum.

During the normal transition from fetal to postnatal circulation, PVR decreases significantly with the baby's first breaths. As this progresses, the ductus arteriosus gradually closes, removing this as an additional source of pulmonary blood flow. During this time pulmonary valve stenosis may become evident. The clinical manifestations of this lesion occur along a continuum based on the degree of valvar obstruction. Mild narrowing of the pulmonary valve is associated most often with a crescendo systolic ejection murmur, acyanosis, and few related symptoms. A more harsh and later peaking murmur is common with more advanced stenosis and can be associated with cyanosis from right-to-left shunting through a PFO/small ASD or from inadequate pulmonary blood flow in the absence of a PDA. Importantly, until closed, left-to-right shunting through the PDA can delay presentation of significant valvar stenosis by providing an additional source of pulmonary blood flow thereby delaying the appearance of central cyanosis.

The progression of pulmonary valve stenosis is typically not as malignant as with aortic valve stenosis caused by the lower resistance of the vascular bed beyond the affected valve. Less than 30% of newborns diagnosed with mild pulmonary valve stenosis will develop moderate or severe gradients; this occurs in only 15% of those presenting after 1 month of age. Intervention is typically reserved for those children with inadequate cardiac output or a transpulmonary valve gradient of greater than 50 mm Hg. In most centers, the standard of care for pulmonary valve stenosis is balloon valvuloplasty in the cardiac catheterization lab. This procedure is typically very well tolerated with rare complications, and gradient reductions to less than 15 to 20 mm Hg can be achieved in more than 90% of patients. The risk of restenosis is low following balloon valvuloplasty for isolated pulmonary valve stenosis, while progressive pulmonary valve insufficiency is the greater concern. One series documented moderate to severe pulmonary valve insufficiency in 57% of

patients following an average of 12 years post-intervention. However, even severe insufficiency of the pulmonary valve is relatively well tolerated because of the lower pressures associated with the pulmonary circulation. Nonetheless, periodic follow-up with a cardiologist will be required to assess for recurrence of valvar or subvalvar obstruction as well as the development of clinically important pulmonary insufficiency.

**EBSTEIN ANOMALY.** Ebstein anomaly is characterized by apical displacement of the tricuspid valve's septal leaflet, resulting in both tricuspid valve insufficiency and atrialization of a section of the right ventricle (Figure 234-12, A). Ebstein anomaly has a wide spectrum of severity, ranging from diagnosis at postmortem examination in adulthood to presentation in infancy requiring single-ventricle palliative surgery. When significant, this anomaly is commonly a right-to-left shunting lesion in the newborn period when PVR remains elevated. The course of blood flow is much the same as in pulmonary atresia with intact ventricular septum. With worsening tricuspid valve incompetence, the effectively smaller right ventricle is less able to propel blood across the pulmonary valve, which is usually narrowed or stenotic, or both. This blood instead returns to the right atrium and crosses the patent foramen ovale. Effective pulmonary blood flow is then dependent on the PDA. Chest radiograph usually demonstrates marked cardiomegaly from right-atrial dilatation (Figure 234-12, B). These children are closely monitored until their PDAs close and PVR has decreased at which time the degree of forward pulmonary blood flow can be reassessed and a more definitive care plan can be made.

The short- and intermediate-term outcomes of children with this diagnosis are determined, in part, by the severity of disease (ie, degree of cyanosis) at presentation. When clinical symptoms are present shortly after birth and unacceptable cyanosis is unremitting ( $\text{SaO}_2$  less than 70%–75%), the single-ventricle treatment algorithm is generally required, with outcomes similar to those of children with hypoplastic left heart syndrome. Conversely, fetal diagnosis with early severe tricuspid regurgitation can be associated with pulmonary hypoplasia secondary to severe right-atrial enlargement. Severely hypoplastic lungs will preclude cardiac palliation, and most of these infants succumb shortly after birth. Newborns with acceptable saturations and adequate cardiac output can be discharged from the hospital and followed expectantly with intervention that may be necessary only during older childhood or adolescence when exercise intolerance or pronounced exercise-associated cyanosis develops.

**TOTAL OR PARTIAL ANOMALOUS PULMONARY VENOUS RETURN.** Embryologically, total anomalous pulmonary venous return (TAPVR) occurs when the pulmonary veins do not connect with the posterior wall of the left atrium. They instead form a confluence that then drains via a vertical vein indirectly to the right atrium. This vertical vein returns to either a supracardiac or infracardiac structure, generally the innominate or hepatic veins, respectively. Blood then returns to the right atrium and is shunted right to left through an obligate ASD into the left atrium providing

**Figure 234-12** A, Apical 4-chamber echocardiographic view of a newborn with Ebstein anomaly of the tricuspid valve. The double arrow points to the apically displaced septal and posterior tricuspid valve leaflets, which result in ineffective coaptation of the tricuspid valve. The short arrow depicts right-to-left bowing of the atrial septum caused by the high right-atrial pressure from the regurgitant tricuspid valve volume. The perforated arrow demonstrates the relative size of the normal mitral valve. B, Chest radiograph of the same patient depicting cardiomegaly caused by severe right atrial enlargement.

the only source of systemic cardiac output. Conversely, partial anomalous pulmonary venous return (PAPVR) is the anomalous return of 1 or more pulmonary veins to the right heart. Unless more than 1 of the pulmonary veins returns anomalously, this anomaly rarely becomes hemodynamically significant and may not require surgical correction unless symptoms develop (ie, exercise intolerance).

The diagnosis of TAPVR or PAPVR can be difficult to confirm by echocardiogram and, particularly in cases of complex anatomy, may require cardiac catheterization or magnetic resonance imaging if clinically suspected. Infradiaphragmatic drainage often becomes obstructed at some point along the extended, tortuous course of the vertical vein into the liver and, when present, constitutes a surgical emergency. Surgical correction for uncomplicated TAPVR consists of reanastomosis of the pulmonary venous confluence to the posterior wall of the left atrium. The most common postoperative complications are obstruction at the site of the anastomosis, pulmonary vein stenosis, and left-atrial dysrhythmias. Periodic long-term cardiology follow-up is necessary since, if unrecognized, prolonged obstruction of the anastomosis or pulmonary veins can result in irreversible pulmonary venous obstructive disease, pulmonary vascular disease, and eventual right-heart failure.

### Dextrorotation or Rightward Transposition of the Great Arteries

Dextrorotation or rightward transposition of the great arteries is an embryologic defect of the conotruncus in which the aortic valve is positioned rightward and anterior to the pulmonary valve instead of rightward

and posterior as in the normal heart. This anatomic arrangement results in a right-ventricular connection with the aorta and a left-ventricular connection with the pulmonary artery. Thus, the pulmonary and systemic circulations are in parallel rather than in series and result in prohibitive cyanosis unless adequate mixing of the 2 circulations is established.

To provide adequate mixing, bidirectional flow through a PFO or ASD is necessary. If inadequate (ie, low  $\text{SaO}_2$  or partial pressure of oxygen), the physician must consider whether a balloon septostomy (Rashkind procedure) of the atrial septum is necessary to increase blood exchange and systemic oxygen delivery. Patency of the ductus arteriosus can supplement the volume of blood exchange by increasing the blood return to the left atrium, which permits better mixing at the atrial level but is usually insufficient to achieve acceptable saturations in the absence of a large interatrial communication.

In general, oxygen-poor blood is shunted from the aorta to the pulmonary artery via the PDA, which results in equal, 4-extremity cyanosis. Conversely, if persistent fetal circulation exists, with PVR greater than SVR, then oxygenated blood will shunt from the pulmonary artery to the aorta producing paradoxical cyanosis with higher  $\text{SaO}_2$  in the legs (downstream from the ductus) compared with the arms and brain. Therefore, adequacy of upper extremity (and brain)  $\text{SaO}_2$  must be assessed; this is typically done by monitoring pre- and post-ductal saturations.

### Clinical Signs and Symptoms

Dextrorotation or rightward transposition of the great arteries can be diagnosed prenatally and is the most

common type of cyanotic heart disease. These patients generally are cyanotic at birth without associated respiratory distress. Physical examination will therefore be remarkable for cyanosis and possibly a ductal murmur, but should otherwise be normal for a newborn.  $\text{SaO}_2$  will not increase significantly with supplemental oxygen (failed hyperoxia challenge test). Care should be taken to assess lower extremity pulses as coarctation of the aorta can be associated with dextro-looped transposition of the great arteries (d-TGA). Prostaglandin E1 infusion should be initiated once this defect is suspected.

### Evaluation

**ELECTROCARDIOGRAM.** The ECG will generally be unremarkable for a newborn and will not offer added information unless other cardiac defects exist.

**CHEST RADIOGRAPH.** The classic radiographic finding for d-TGA is the *egg on a string*. The great arteries are often oriented anterior-posterior (the string) instead of perpendicular, removing the aortic and pulmonary knobs. This great artery orientation can also create a mesocardic orientation of the heart, producing an egg-shaped cardiac silhouette.

**ECHOCARDIOGRAM.** Two-dimensional echocardiogram will confirm the diagnosis and can evaluate the extent of intra- and extracardiac shunting. ASD size, direction of ductus arteriosus shunting, and presence of a VSD are important components of intercirculatory mixing. Furthermore, coronary artery anomalies are common with this CHD and can complicate the surgical repair. Therefore, coronary anatomy and abnormalities of the aortic arch should be fully delineated prior to surgical repair.

### Management

Transposition of the great arteries can be one of the more complex CHDs to manage in the newborn period. The single most important component of preoperative management is maintaining adequate atrial-level shunting. Although the presence of a VSD is important when considering surgical options, ventricular-level shunting does not usually contribute a significant amount of intracardiac mixing in the newborn period.

Many patients with d-TGA have already begun receiving prostaglandin E1 infusions at the time of diagnosis after failing the hyperoxia challenge. Continued assessment for paradoxical cyanosis (as seen with persistent fetal circulation),  $\text{SaO}_2$ , and arterial oxygen content are necessary. In general, an arterial oxygen content greater than 30 mm Hg (typical fetal partial pressure of oxygen in arterial blood [ $\text{PaO}_2$ ]) with a corresponding  $\text{SaO}_2$  of more than 75% to 80%, in the absence of metabolic acidosis, are predictive of adequate atrial-level mixing and systemic oxygen delivery. If these conditions are not met and the newborn demonstrates any signs of respiratory distress with marked cyanosis, then the ASD is likely restrictive and needs to be enlarged. This task can be accomplished by balloon septostomy, blade septostomy, or radiofrequency ablation of the atrial septum in the catheterization laboratory. Although these procedures are necessary life-saving interventions, they can be associated with significant risks of morbidity and mortality.

### Surgical Correction

With the advent of microsurgical techniques came the ability to reimplant coronary arteries (Figure 234-13). This procedure allowed for the successful arterial switch (Jatene) operation, which has been the surgical option of choice for most patients with d-TGA since the 1980s. As a result, the atrial switch operation (Mustard and Senning procedures) has largely become obsolete. The process of switching the great arteries is conceptually intuitive but technically very complex. Once the patient is placed on cardiopulmonary bypass, the aortic and pulmonary arteries are transected above their native valves. Next, the surgeon removes the coronary arteries from the aortic root (arising from the right ventricle) by cutting small buttons of tissue surrounding the ostium of each coronary artery. Similarly sized buttons of tissue are removed from the pulmonary artery (arising from the left ventricle), and the coronary arteries are sutured into the native pulmonary artery root (arising from the left ventricle). The aorta is freely mobile within the thorax and readily sutured to the exposed pulmonary artery root. The main and branch pulmonary arteries remain attached to the lungs and are subsequently more restricted in their range of motion. To minimize surgical stretch and subsequent obstruction, the Lecompte maneuver is performed, which drapes the main and branch pulmonary arteries over, instead of underneath, the ascending aorta.

Abnormal coronary artery anatomic configuration is relatively common, occurring in approximately 30% of all patients with d-TGA. This abnormality can produce one of the major complications of the arterial switch operation. A single coronary artery origin of both the right and left coronary arteries necessitates *flipping* of the button before reimplantation and is often associated with kinking and compromise of coronary artery flow. Although no coronary pattern precludes a *switch*, transmural (coursing through the arterial wall) coronary artery anatomy and others may increase the risk of the procedure, necessitating alternative surgical approaches. Discordant annulus size of the great arteries can also produce difficulty but is often not an absolute contraindication to an arterial switch. Compared with long-term atrial switch results, the outcomes data for patients with d-TGA after an arterial switch operation are substantially better, but significant morbidity persists. An overall mortality rate of 7% was reported in a study of 223 patients with d-TGA after the arterial switch operation; coronary artery pattern was not associated with an increased risk of death. However, 2 studies with a total of 1,263 patients demonstrated a rate of coronary artery events between 7% and 8% over 15 years of follow-up. Abnormal coronary artery vasomotor function has also been demonstrated in asymptomatic children after the arterial switch operation. Furthermore, a retrospective study of 119 postoperative patients with d-TGA followed for a median of 65 months found progressive aortic root dilatation without an increased prevalence of aortic insufficiency. The clinical significance of these findings requires further study. Though the arterial switch operation remains the best surgical option available, this patient population requires continued long-term follow-up by

**Figure 234-13** Stages of the arterial switch operation used in patients with d-TGA. The first picture demonstrates transection of the aorta and pulmonary artery just distal to their respective valves. In the middle picture, the coronary artery buttons are rotated from the original aortic root to the *neoaortic* root and sutured into place.

a cardiologist who can periodically evaluate for postoperative morbidities including those mentioned above as well as supravale and branch pulmonary stenosis related to the LeCompte maneuver.

### Left-Sided Obstructive Lesions

Left-sided obstructive lesions are characterized by impedance to blood flow from the systemic ventricle (generally the left) to the body. As with nearly all heart lesions, the severity of the obstruction determines the age of presentation and clinical manifestations.

#### Aortic Stenosis

Valvar aortic stenosis can occur in isolation or be associated with either subvalvar or supravalar obstruction. With the exception of an audible click heard in valvar stenosis, the presentation and alteration of cardiovascular physiologic characteristics are very similar among the 3 defects. When the stenosis is mild or moderate, a cardiac murmur may be the only sign of an abnormality in the newborn period. However, depending on ductal dependency, a severe or critical degree of aortic stenosis, is associated with inadequate cardiac output and will present in the newborn period as heart failure or clinical extremus.

A large portion of fetal cardiac output is provided by ductal flow from the pulmonary artery to the descending aorta. The transition to postnatal circulation occurs with closure of the ductus arteriosus. In the newborn with severe or critical aortic stenosis, this process is associated with a significant decrease in systemic blood flow. Although the output will be fully

oxygenated, the volume will be inadequate, and evidence of congestive heart failure and low cardiac output will ensue. Diaphoresis with feeding, irritability, lethargy, and fatigue will bring these children to a physician's attention. The infant will be acyanotic but ashen, and will have a systolic ejection murmur of variable intensity and harshness (depending on cardiac output) and diminished or absent peripheral pulses. Increasing severity of stenosis is therefore associated with increased dependence on ductal flow for systemic cardiac output, which is then associated with an earlier presentation.

Several studies have demonstrated that valvar aortic stenosis severity can change dramatically during the first 6 months of life and that final valvar gradients are poorly predicted by initial gradients. Most pediatric cardiologists will monitor infants with aortic stenosis on a frequent basis to plan timely intervention for rapidly progressive stenosis before congestive heart failure and systemic shock occur. Children not requiring intervention before 6 months of life are less likely to develop heart failure or become critically ill during the follow-up period.

Milder degrees of aortic stenosis may not present until childhood. These patients will typically be asymptomatic, and examination will reveal an ejection click followed by a harsh systolic ejection murmur best auscultated at the right upper sternal border. ECG evaluation of these patients may or may not demonstrate signs of left-ventricular hypertrophy and is unlikely to show any signs of myocardial ischemia. Particularly in the pediatric population, mild to

moderate aortic stenosis will not produce exercise intolerance, chest pain, syncope, or shock. As a result, these children are often referred to a pediatric cardiologist after the characteristic murmur is heard during a routine physical examination.

### Evaluation

**ELECTROCARDIOGRAM.** ECG findings associated with aortic stenosis depend on disease severity. In the newborn with critical stenosis, ST segment elevation or depression, T wave inversion, and sinus tachycardia may be present; right-ventricular hypertrophy is usually noted, and voltage criteria for left-ventricular hypertrophy may already be present or develop quickly. As mentioned previously, mild-to-moderate disease will likely demonstrate voltage criteria for left-ventricular hypertrophy, but ST or T wave changes are less likely.

**CHEST RADIOGRAPH.** A chest radiograph is helpful only if pulmonary edema has developed because of left heart failure. The anteroposterior (AP) projection of the cardiac silhouette is usually not particularly helpful.

**ECHOCARDIOGRAM.** Two-dimensional echocardiogram is adequate to make the diagnosis of aortic stenosis. Hyperdynamic systolic function of a hypertrophied left-sided ventricle may be found. A bicuspid aortic valve will be present in nearly 60% of cases. Doppler flow can approximate the systolic flow gradient across the obstructed region. In the setting of subvalvar aortic stenosis, flow acceleration begins below the valve and can be associated with aortic valve regurgitation. Supravalvar aortic stenosis is commonly seen with Williams syndrome and should prompt a search for the associated lesions of coronary ostial stenosis and pulmonary branch stenosis. In the neonate with aortic stenosis, patency of the ductus arteriosus and its direction of flow are important to help plan an appropriate management strategy.

### Management

Balloon valvuloplasty became the standard of care for valvar aortic stenosis in the 1990s, when several investigators demonstrated that this approach was equally effective with less morbidity and mortality when compared with surgical valvotomy. However, timing of intervention is perhaps the most difficult element in the management of this disease. As discussed earlier, the progression rate of aortic stenosis during the first 6 months of life is unpredictable. If diagnosed prenatally or shortly after birth in an otherwise healthy, stable newborn, careful monitoring alone is justified. Mild-moderate stenosis with a peak gradient by echocardiogram of less than 50 mm Hg with good LV function and either a closed or left-to-right shunting ductus arteriosus does not generally require urgent intervention, and the newborn can be discharged from the hospital with close follow-up. Right-to-left shunting through the ductus arteriosus suggests ductal-dependent systemic cardiac output (in the absence of persistent fetal circulation), and the child should remain monitored in the hospital until a final decision regarding the need for intervention is reached.

Once the infant is home, most pediatric cardiologists will arrange biweekly or monthly visits for the first 6 months of life. During this rapid phase of somatic growth, changes in clinical status or aortic stenosis gradient can occur quickly. When neonatal intervention is required, frequent return visits may occur for at least the first 6 months of life because the frequency of restenosis is between 15% and 30%.

In most cases, aortic valvotomy, whether performed in the catheterization laboratory or in the operating room, results in some degree of aortic insufficiency. Separation of fused commissures allows for less encumbered prograde flow but also disrupts intrinsic leaflet coaptation. Fortunately, the degree of insufficiency is usually mild and is well tolerated for many years.

Valvar aortic stenosis tends to increase at a slower, more predictable rate after the first year of life. Non-emergent intervention is indicated in the setting of progressively severe left-ventricular hypertrophy with a transvalvar gradient (found at catheterization) above 50 mm Hg. Most cardiologists would also intervene in the presence of syncope, exercise intolerance, chest pain, or an abnormal exercise stress test. For isolated valvar stenosis, balloon valvuloplasty is the preferred interventional procedure. However, if stenosis is also accompanied by significant valvar insufficiency, or if severe insufficiency develops after a balloon procedure with associated LV dilatation and dysfunction, then surgical intervention will be the only effective therapy. Surgical options include valve replacement with a prosthetic mechanical valve, cadaveric homograft, porcine xenograft, or a pulmonary valve autograft (Ross procedure). When deciding which option is best, the important considerations are the child's age, size, lifestyle, and future adherence to an anticoagulation regimen.

With the exception of an absent valve click, subaortic stenosis is clinically indistinguishable from valvar stenosis. However, the pathophysiologic circumstance is different in several important ways. In subvalvar aortic stenosis, the left-ventricular outflow tract (LVOT) is obstructed by a superfluous tissue membrane, hypertrophy of the IVS immediately below the aortic valve, or both. The blood flow velocity becomes accelerated before reaching the aortic valve and gradually damages the leaflets over time, which can result in progressive valvar regurgitation. Surgical resection of this subaortic region is indicated to relieve obstruction and prevent progressive aortic valve damage and resultant insufficiency. A recurrence rate of 20% to 30% for subaortic obstruction after resection coupled with an inability to predict significant valve damage accurately makes the decision to intervene extremely difficult. In general, surgical resection is performed with the onset of any degree of aortic insufficiency or outflow gradients between 20 to 40 mm Hg. Furthermore, the rate of progression of subaortic stenosis is insidious and is not associated with acute cardiovascular decompensation. Progressive valvar damage can ultimately require valve repair or replacement with a homograft valve, artificial valve, or autograft valve via the Ross procedure.

Supravalvar aortic stenosis is the least commonly encountered form of aortic stenosis. Its frequent association with Williams syndrome also places these patients at increased risk for supravalvar branch pulmonary stenosis and obstruction at the origin of other major vessels (ie, coronary arteries, subclavian arteries, carotid arteries, splenic arteries; Figure 234-14). As with subvalvar aortic stenosis, this anatomic variant has an insidious disease progression marked by significantly elevated coronary artery perfusion pressures. Furthermore, given that the pressure gradient is located superior to the aortic root, the proximal portions of the coronary arteries are dilated in response to the persistently elevated pressures they experience. When surgery is indicated, patch aortoplasty of the narrowed region is corrective but also reduces the coronary artery perfusion pressure and can produce coronary artery ischemia if not proactively managed in the postoperative cardiac intensive care unit.

### Coarctation of the Aorta

Coarctation can occur as a discrete narrowing or in association with diffuse hypoplasia of the transverse and aortic arch isthmus often in the presence of a bicuspid aortic valve. Although a discrete coarctation can occur in virtually any portion of the aorta, it is typically found near the insertion of the ductus arteriosus (juxtaductal). Patient presentation tends to have a bimodal distribution; those with diffuse arch hypoplasia are typically diagnosed shortly after birth, and those with an isolated discrete narrowing may not be diagnosed until later in infancy or childhood (Figure 234-15).

**Figure 234-14** Aortogram of a 2-year-old child with non-Williams congenital supravalvar aortic stenosis (*long arrow*) with coarctation of the aorta (*short arrow*). The perforated arrow demonstrates the narrowed origin of the left subclavian artery.

**Figure 234-15** Infantile and adult types of coarctation of the aorta. The left picture demonstrates a diffusely hypoplastic aortic arch extending into the proximal descending aorta at the insertion of the ductus arteriosus. The right picture shows a more discrete area of narrowing with a large collateral vessel spanning the coarctation site.

In children with severe coarctation, a tissue ledge protrudes from the posterior wall into the lumen of the isthmus of the aorta. During the transition from fetal circulation, the ductus arteriosus tissue begins to contract in response to rising oxygen concentrations. Constricting ductal tissue in combination with the adjacent posterior ledge forms an obstructive shelf. If this shelf of tissue is significantly obstructive to limit lower body flow, then systemic underperfusion and shock can ensue. Once diagnosed, infusion of prostaglandin E1 can reopen the ductus and provide ductal flow to the lower body, minimize the juxtaductal obstruction to flow, or both.

Aortic coarctation diagnosed during adolescence has a distinctly different presentation. The fact that these children survive through infancy without either detection or intervention suggests a different pathophysiology. The most likely difference is that a discrete, relatively undersized segment of the aorta, which was adequate for early postnatal life, did not continue to grow at a rate commensurate with the remainder of the aorta. Given that the segment never becomes acutely obstructive, the body has time to produce multiple collateral arteries connecting the aorta proximal and distal to the obstruction thus bypassing the coarctation. If undetected for many years, the intercostal arteries supplying the collateral artery system can become extensive and produce indentations or notching of the ribs. Unlike the neonatal presentation, these patients exhibit only a systolic murmur, upper extremity hypertension, or both. Upper extremity or pre-coarctation hypertension is the result of increased pressure proximal to the obstruction and increased renin-angiotensin activity intended to maintain normal perfusion pressure to the renal arteries. Any evaluation of pediatric hypertension should include an evaluation for coarctation of the aorta.

### Evaluation

**ELECTROCARDIOGRAM.** As with aortic stenosis, the ECG is unlikely to contribute to the diagnosis of coarctation of the aorta unless left-ventricular hypertrophy or strain is present.

**CHEST RADIOGRAPH.** In the adolescent with longstanding, unrepaired coarctation of the aorta, rib notching may be seen from engorgement of the intercostal blood vessels, which will provide collateral circulation around the coarctation segment.

**ECHOCARDIOGRAM.** Two-dimensional echocardiogram can be used to diagnose the presence of a hypoplastic aortic arch or discrete narrowing of the aorta. Although Doppler flow can estimate the blood pressure gradient, upper and lower extremity blood pressures are perhaps a more accurate modality for determining the clinical coarctation gradient. As with aortic stenosis, the echocardiogram should be used to evaluate for any other left-sided obstructive lesions to help guide management.

### Management

The newborn with coarctation of the aorta may present in several different ways. Because this lesion may not be detected by prenatal ultrasound, palpation of

the femoral pulses becomes a crucial part of the newborn examination. When not palpable in an otherwise healthy-seeming infant, both upper and one lower extremity blood pressure should be obtained with the infant supine and calm. Blood pressure should be checked in both arms because the left subclavian artery may arise either proximal or distal to the coarctation site. Although rare, if it arises distal to the coarctation and only the left arm was monitored, then no blood pressure gradient would be demonstrated because both the leg and left arm would have postobstruction blood pressures. However, checking only a right arm blood pressure can be misleading as well. In the case of an aberrant right subclavian artery arising distal to an aortic coarctation, both the leg and right arm would again have postobstruction blood pressures and would not demonstrate a blood pressure gradient. Other than isolated, unilateral femoral artery stenosis, no circumstances are found in which a blood pressure gradient exists between the lower extremities; therefore a single leg blood pressure should be adequate.

If a gradient is demonstrated by blood pressure cuff, then a pediatric cardiology consultation should be obtained. Although extremity blood pressures are far more accurate in determining the actual gradient across the coarctation, an echocardiogram is needed to determine if the coarctation is ductal dependent and to evaluate for other left-sided obstructive lesions. Determining the presence of a PDA is of critical importance. Additionally, because of the presence of ductal tissue in the aorta, a coarctation cannot be excluded with certainty until the ductus has closed. If the ductus is closed and a blood pressure gradient by cuff or narrowing by echocardiogram is not found, then a hemodynamically significant coarctation does not exist. Therefore, if concerns for the existence of a coarctation are present, then the patient should not be discharged until the ductus arteriosus has completely closed or close follow-up has been arranged.

Hemodynamically significant (ductal-dependent) coarctation of the aorta in the newborn period requires intensive management. The initial treatment should be initiation of a prostaglandin E1 infusion to maintain ductal patency or regain it should the ductus be closed or small. The patient should receive no enteral feeds because of possible intestinal underperfusion, and renal function should be monitored closely. For the discharged newborn whose ductus closed at home insidiously, resulting in a coarctation, shock is likely to be present from poor lower body perfusion. These patients should be treated similarly but will also require frequent blood gas monitoring for assessment and correction of acidosis, possible mechanical ventilation, upper and lower extremity blood pressures to track the success of the prostaglandin infusion in regaining ductal patency, as well as possible inotropic support. If the physician is unable to reestablish adequate lower body perfusion, then emergent intervention may be required.

**SURGICAL MANAGEMENT.** Though balloon aortoplasty has been used in treating infant native coarctation of the aorta, most pediatric cardiologists consider surgical correction the standard of care. The surgical

**Figure 234-16** Subclavian flap repair of a discrete coarctation of the aorta.

technique used depends on the extent of the coarctation and surgeon preference. Historically, for discrete coarctations, the 2 most common surgical approaches were subclavian flap repair and patch aortoplasty. In the former, the subclavian artery closest to the coarctation (generally the left) is ligated distally and filleted open (Figure 234-16). The coarctation region is also filleted open, and the flap of subclavian artery tissue is then rotated and sutured in place. The alternative to ligation of the subclavian artery is use of a patch to open the coarctation. Of the 2 approaches, use of the subclavian flap procedure is less likely to result in aneurysmal dilatation of the segment of aorta but, until adequate arterial collateralization occurs, can be associated with a mild growth retardation and loss of strength in the respective arm.

Currently, for both standard discrete coarctations and those in which the coarctation is associated with some element of isthmic hypoplasia, particularly in infants, the preferred surgical approach is coarctation segment resection with *extended end-to-end* reanastomosis. By beveling the 2 ends before anastomosis, the circumferential sutures are distributed over a larger area and are less likely to fibrose and form a recoarctation. The rate of recoarctation varies but is reported between 5% and 25%.

Coarctation associated with a diffuse segment of transverse arch hypoplasia is generally not amenable to an extended end-to-end reanastomosis unless the descending aorta can be fully mobilized and advanced proximally to the distal ascending aorta without disrupting cervical vessels. In these instances, arch repair will be quite extensive and usually requires arch augmentation with homograft material that is sewn around the lesser curvature of the arch, from the transverse arch beyond the resected coarctation segment to the proximal descending aorta to reduce the risk of subsequent restenosis.

The actual surgical incision site may change based on the extent of the coarctation. A discrete region of

affected aorta without associated intracardiac malformations will generally be repaired through a lateral thoracotomy. An intercostal incision is made in the mid-axillary line and visualization is achieved by separation of the left upper and lower lung lobes. When diffuse aortic hypoplasia or intracardiac malformations exist, a midline sternotomy approach is preferred to maximize exposure and ability to repair the defect adequately.

**PROGNOSIS AFTER SURGERY.** Given a potentially significant restenosis rate after initial repair, balloon dilatation in the cardiac catheterization laboratory is an invaluable tool for these patients. A gradient of more than 20 mm Hg is generally considered the clinical indication for intervention. Balloon dilatation results in splitting or tearing of intimal or proximal medial tissue planes and will often be repeated 2 to 3 times to ensure adequate luminal diameter. Several studies have demonstrated postballoon dilatation restenosis rates of less than 20%, but associated transverse arch hypoplasia was associated with a higher rate of reintervention. Stent placement during balloon dilatation has been shown to reduce the rate of restenosis and provide significant relief from obstruction in intermediate follow-up studies (3–6 years). However, these studies predominantly evaluated adults. Stent placement in the proximal descending aorta of young children is not commonly employed, however, because these stents cannot typically be adequately dilated to compensate for growth.

Postoperative or postprocedural treatment of coarctation of the aorta is often complicated by paradoxical hypertension or systemic blood pressure higher than preoperative measures. Animal studies have shown that stimulation of sympathetic nerve fibers located between the media and the adventitia of the aorta increases norepinephrine release, which increases systemic blood pressure. The spinal reflex is a positive feedback loop, which responds to this hypertension by increasing renin secretion from the juxtaglomerular cells of the kidney. These findings have been supported by human data

in patients immediately after coarctation repair. A persistent hyperdynamic state of the left ventricle likely plays a causative role as well. On this basis,  $\beta$ -blocker medications are often employed to treat hypertension in the immediate postoperative period. When hypertension persists beyond the first few postoperative days, most physicians will use angiotensin-converting enzyme inhibitors to offset the renin-mediated phase of hypertension. Finally, some research suggests that dysfunctional vasodilatory mechanisms may play a large role when systemic hypertension persists after postoperative recovery. Although less likely in infants and young children, patients who undergo coarctation repair during or after adolescence have demonstrated a higher rate of persistent hypertension, which may be caused by an inability to adapt to the spinal reflex described previously. Routine cardiology follow-up will be necessary even after a “perfect” coarctation repair to assess for possible associated longer-term morbidities including persistent systemic hypertension (less likely if repaired as an infant), recoarctation or arch aneurysm (depending on type of surgical repair performed), progressive aortic valve disease (bicuspid valve can become stenotic or regurgitant), occurrence of symptomatic cerebral aneurysms, and coronary artery disease.

### Complete Mixing Lesions or the Single-Ventricle Heart

By definition, a complete mixing lesion is one in which the  $\text{SaO}_2$  of blood is the same in both the aorta and the pulmonary arteries. Systemic and pulmonary venous blood volumes drain into a single ventricle, and this combination of oxygen-rich and oxygen-poor blood produces a partially desaturated blood volume perfusing both the body and the lungs. Hypoplastic left heart syndrome will be used as the prototype for this classification of heart lesions, but the physiologic mechanism and management is applicable to most variations of the single-ventricle heart.

#### Hypoplastic Left Heart Syndrome

Hypoplastic left heart syndrome (HLHS) is a group of cardiac anomalies characterized by underdevelopment

of the aortic arch, aortic valve, mitral valve, and left ventricle. Embryologically, this series of anomalies is likely propagated by inadequate blood flow through a stenotic or atretic aortic valve. Inadequate prograde flow through the left ventricle results ultimately in diminished growth. Fortunately, in utero, the fetal circulation can be adequately supplied by the right ventricle, and normal somatic growth continues. Therefore, most newborns with HLHS are able to achieve normal birth weight and gestational age.

Unless diagnosed prenatally, the newborn with HLHS may not be immediately recognized, and, unless systemic saturations are monitored or cyanosis is noted, these infants may not be diagnosed during their newborn hospitalization. The timing of presentation is dependent on closure of the PDA in conjunction with the delicate balance between pulmonary and systemic blood flow. All egress of blood from the single, right ventricle occurs through the pulmonary artery. Blood within the main pulmonary artery will flow to either the lungs or through the PDA into the descending aorta and retrograde into the ascending aorta (Figure 234-17). Since all systemic output is ductal dependent, as the PVR decreases and pulmonary blood flow increases, systemic blood flow is decreased. Untreated, the oxygen-sensitive ductal tissue begins to constrict, further decreasing systemic blood flow. This condition will result in pulmonary overcirculation and systemic shock and is typically the state in which previously undiagnosed patients with HLHS present. When the condition results in end-organ damage or a delay in surgical intervention, morbidity and mortality increase significantly.

#### Evaluation

**CHEST RADIOGRAPH.** Unless pulmonary overcirculation occurs, radiography is unlikely to contribute much to the diagnosis of HLHS except, possibly, to differentiate a cardiac from a pulmonary source of cyanosis.

**ELECTROCARDIOGRAM.** The healthy newborn's ECG will demonstrate right-ventricular hypertrophy with a right-axis deviation as a result of its hypertrophy relative to the left ventricle. This pattern will

**Figure 234-17** A, Comparison of the anatomy and relative structure sizes between a normal, 4-chambered heart and a hypoplastic left heart with atresia of both the mitral and aortic valves. B, These 2 figures depict the relative blood flow between the pulmonary and systemic circulations in a patient with HLHS. The left-sided drawing shows the relative blood flows in a patient with mildly elevated PVR and systemic  $\text{SaO}_2$  levels of 70% to 80%. When PVR is decreased, however, systemic  $\text{SaO}_2$  levels increase to 90% with a concomitant increase in pulmonary blood flow and a decrease in systemic blood flow.

continue with the newborn with HLHS, but it may be more pronounced. A distinguishing feature may be a relative paucity of left-ventricular forces in the lateral precordial leads.

**ECHOCARDIOGRAM.** Echocardiogram is the confirmatory study. The sonographer should document the presence or absence of the PDA and flow through both the aortic and mitral valves, estimate the left-ventricular volume, determine the size of the ascending aorta and ASD (to verify no significant restriction), and characterize the aortic arch and coarctation. Furthermore, size and competency of the pulmonary and tricuspid valves, and right-ventricular function are critical information to obtain to stratify surgical morbidity and mortality risks (Figure 234-18).

### Management

The first step in management of HLHS is defect recognition. Early clinical manifestations can be subtle. The newborn with HLHS may not demonstrate profound systemic cyanosis until the  $\text{SaO}_2$  falls below approximately 85% (or lower in dark-skinned children). A cardiac murmur is commonly not present or appreciated. Therefore, palpation of femoral pulses becomes a critical step in every newborn's routine evaluation (see chapters in Part 4: Care of Healthy and High-Risk Infants). As with isolated coarctation of the aorta or critical aortic stenosis, the newborn with HLHS will commonly have decreased femoral pulses. These pulses will become progressively weaker as the ductus arteriosus closes. If aortic atresia exists, then all 4 extremity pulses will diminish with ductal closure.

**Figure 234-18** Apical 4-chamber echocardiographic view of a newborn with HLHS. Notice the severely underdeveloped left atrium and left ventricle.

Once a clinical suggestion for the diagnosis of HLHS exists, a prostaglandin E1 infusion should be started immediately. Starting doses can vary widely based on clinical status, but all can result in apnea. If a cardiac lesion is strongly suspected, beginning a prostaglandin E1 infusion should not be delayed awaiting pediatric cardiology consultation.

When the diagnosis of HLHS is confirmed, arterial and venous catheters should be inserted, if possible. The specific preoperative medical management of these newborns varies between institutions. However, the parameters directing management are the same and include renal function (assessed by urine output and serum creatine), blood pressure,  $\text{SaO}_2$ , and arterial blood gases. When followed serially, these measurements provide a surrogate for the balance between pulmonary and systemic blood flow. If renal function and blood pressure are decreased with a concomitant rise in serum lactate, then systemic oxygen delivery is inadequate. This circumstance generally occurs in the presence of increased  $\text{SaO}_2$  or a relative pulmonary overcirculation. Multiple strategies exist to remedy this situation, including hypoxia (ie, producing subambient oxygen by increased nitrogen infusion into the inhaled gas mixture), hypercarbia (ie, increasing carbon dioxide content of inhaled gas mixture), permissive hypercapnea (ie, when intubated, decreasing minute ventilation with resultant pulmonary vasoconstriction), or decreasing SVR via vasodilatory medications (ie, milrinone, nitroprusside and phenoxybenzamine). Regardless of which method is used or whether the patient is intubated, the primary endpoints of the preoperative therapy are to provide balanced pulmonary and systemic blood flow.

The surgical intervention strategy for all single-ventricle hearts is based on 2 simple premises: (1) A single ventricle is not able to perform the function of 2 ventricles indefinitely, and (2) the PVR is elevated initially after birth and, in most cases, does not decrease completely for weeks to a couple months. The physiologic characteristic does not change regardless of which ventricle is hypoplastic. However, the surgical options available to each patient depend on how blood flow is provided to the lungs and body.

Again, using the HLHS as the prototype for the single-ventricle heart, Figure 234-19 demonstrates the first-stage palliative surgery called the Norwood procedure. This procedure, introduced by Dr William Norwood in 1980, produces a neo-aorta from the main pulmonary artery and the hypoplastic ascending aorta. The main pulmonary artery is ligated at its branch bifurcation point and then attached to the ascending aortic arch, usually in a side-to-side fashion. After resection of a coarctation segment, the remainder of the hypoplastic aortic arch is augmented with homograft. As a result, the pulmonary valve becomes the systemic semilunar valve, and the coronary arteries, which arise normally from the aortic root, are perfused retrograde through the ascending aorta. The surgery is completed by providing pulmonary blood flow through either an aortopulmonary shunt (ie, Blalock-Taussig shunt from the innominate artery to right pulmonary artery) or a right ventricle-to-pulmonary artery conduit (ie, Sano conduit). The right

**Figure 234-19** Depiction of the steps involved in the Norwood procedure. The main pulmonary artery is ligated at its insertion into the confluence of the branch pulmonary arteries. The main pulmonary artery is then connected in a side-side fashion to the hypoplastic ascending aorta. After an appropriately sized homograft patch is made by the surgeon, the new patch material is sewn to the underside of the transverse and proximal descending aortic arch augmenting the previously hypoplastic aortic arch in its entirety to a point beyond the site of native coarctation, which should eliminate any arch obstruction. This process completes the neo-aortic arch reconstruction. Pulmonary blood flow is then provided through a modified Blalock-Taussig shunt, which is a Gore-Tex tube graft connecting the pulmonary arteries to the right subclavian artery.

ventricle is thus transformed into a systemic ventricle responsible for pumping blood to the body and lungs.

This initial palliation is necessary but suboptimal for the single-ventricle heart. The PVR does not fully decline for several months and requires systemic blood pressures to overcome elevated pulmonary artery pressures. The right ventricle is then obligated to perform as both a right and a left ventricle and is also volume overloaded from shunt-mediated pulmonary overcirculation. Once PVR decreases, the second stage of the palliative surgeries decreases the work of the single ventricle by removing the need for active pumping of the pulmonary blood supply. Either the Glenn or hemi-Fontan procedure connects the SVC to the pulmonary artery, and the previously placed shunt or conduit is ligated. By doing so, pulmonary blood flow is provided passively from the SVC into the low-resistance and low-pressure pulmonary arteries (Figure 234-20).

The systemic  $\text{SaO}_2$  in patients after these first 2 palliative procedures will generally remain 75% to 85%. These children will typically have a higher hemoglobin concentration than acyanotic children in

response. The third and final stage of these palliative surgeries is the Fontan procedure, which baffles the IVC to the pulmonary artery, routing all systemic venous return directly into the lungs. Therefore, oxygen-rich is separated from oxygen-poor blood, and the systemic  $\text{SaO}_2$  is typically near normal (>90%).

### Prognosis

A multi-institution study randomizing newborns undergoing the Norwood procedure to receive either a BT shunt or an RV-PA conduit demonstrated 1-year mortality rates of approximately 35% and 25%, respectively. This study underscored the complexity of this patient population, which carries into adulthood. Cardiac dysrhythmias, cerebrovascular accidents with seizures, myocardial ischemia, pleural effusions, and the need for multiple cardiac catheterizations have all been described in this patient population. Improved survival after the Fontan procedure has been shown to be strongly correlated with shorter cardiopulmonary bypass and aortic cross-clamp times. A spectrum of neurodevelopmental outcomes has also been

**Figure 234-20** Depiction of the extracardiac anatomy after the bidirectional Glenn procedure. The Blalock-Taussig shunt is ligated, and the cardiac end of the SVC is divided and anastomosed to the pulmonary arteries becoming the sole source of pulmonary blood flow. The neo-aorta created during the Norwood procedure remains unaltered.

reported for this patient group. Recent studies have shown that most postoperative 8- to 9-year-olds had cognitive scores comparable to the general population, but approximately 18% demonstrated IQ scores under 70. Some of these children have also had varying degrees of developmental motor delay and behavioral problems, including obsessive-compulsive disorder and attention-deficit/hyperactivity disorder. This palliative approach for single-ventricle physiologic arrangement may ultimately serve as an extended bridge to cardiac transplantation, given that some studies have shown that 20% to 30% of patients after undergoing the Fontan procedure develop heart failure, resulting either in successful orthotopic heart transplantation or death.

### Other Complete Mixing Lesions

#### Tricuspid Atresia

Though tricuspid atresia is also considered a single-ventricle anatomy with complete mixing lesion physiology, its clinical manifestations depend on the anatomic variant in each patient. In utero, the atretic tricuspid valve does not allow forward flow into the right ventricle or pulmonary artery, causing them to also become hypoplastic or atretic. As a result, the single ventricle is a left ventricle that is generally connected to the aorta. Distinct types of tricuspid atresia are classified based on the relationship of the great arteries, presence of a VSD, and degree of associated pulmonary stenosis. The most common type consists of tricuspid atresia with normally related great arteries with or without significant pulmonary stenosis. Unless the pulmonary stenosis protects the pulmonary vascular bed by limiting pulmonary artery pressure and flow, an

initial procedure to limit pulmonary blood flow is necessary either via pulmonary artery banding or ligation of the main pulmonary artery and placement of an aorto-pulmonary shunt. In patients who have tricuspid atresia and d-TGA, the aorta arises from the hypoplastic RV and is itself potentially hypoplastic with an associated coarctation. With closure of the PDA, these patients can present in a manner similar to HLHS patients. Like the HLHS patients, this form of tricuspid atresia requires creation of a neo-aorta and placement of an aorto-pulmonary shunt via the Norwood procedure. Since this lesion ultimately follows the surgical single-ventricle reconstruction pathway described for HLHS patients, timing and technique of the Glenn and Fontan surgeries remain unchanged.

## ACQUIRED HEART DISEASE—INFECTIOUS ETIOLOGIES

For a discussion on rheumatic heart disease, see Chapter 323, Rheumatic Fever. For a discussion on Kawasaki disease, see Chapter 280.

### Endocarditis

Endocarditis is a bacterial infection of the endocardium or endothelium of the heart. Generally, endocarditis is associated with a procedural or surgical intervention. Spontaneous endocarditis does occur but is exceedingly rare without predisposing risk factors. Infective endocarditis (IE) is of clinical interest because of the significant morbidity and mortality it produces. With the increased sophistication of interventional catheterization procedures and the dramatic improvement in survival profiles for children with CHD, IE prevalence has risen substantially over the last 2 decades.

Before the 1970s, fewer than 50% of all children with IE had an associated CHD; these children now account for approximately 90% of all cases. The remaining cases are generally associated with indwelling venous catheters without associated structural heart disease.

The pathogenesis for IE is relatively well understood. Intact endocardium will not predispose the area to bacterial attachment or activation of the coagulation pathway. However, cardiac endothelium can be directly damaged by venous catheters or indirectly by the turbulent flow produced with many congenital heart defects. In either situation, thrombogenesis can occur with deposition of sterile clumps of fibrin, platelets, and red blood cells.

Staphylococci, streptococci, and enterococci remain the most common pathogens because of their ability to interact with platelets and resist the host's immune response. The known risks of developing IE in the preoperative state of CHDs are as follows: tetralogy of Fallot, more than 30%; VSD, 12% to 14%; PDA, 8%; aortic stenosis, 2%; and pulmonary stenosis, 1%.

### Diagnosis

The clinical course of IE is typically indolent but, in rare cases, can cause cardiogenic shock. Affected patients may have recurrent low-grade fevers (90%), arthralgias (25%), gastrointestinal discomfort (15%),

fatigue, rigors, or other nonspecific findings. Physical examination may be significant for a new cardiac murmur (rare), splenomegaly (55%), and neurologic changes (20%). The classically described findings of Osler nodes (tender subcutaneous nodules on pads of fingers), Janeway lesions (nontender hemorrhagic macules on palms or soles), Roth spots (pale-centered oval hemorrhages on retina), and splinter hemorrhages in the nail beds are rare in children.

In 1994 the Duke criteria for diagnosis of IE were introduced. Using these lists of major and minor criteria has improved diagnostic accuracy. The Duke criteria for IE are met if a patient demonstrates both major criteria, 5 of the 6 minor criteria, or 1 major and 3 minor criteria. Because direct visualization of infected thrombi is difficult, most physicians require 2 distinct blood cultures with identical bacterial pathogens before considering the diagnosis of IE. Although transthoracic echocardiography (TTE) has excellent specificity, the poor sensitivity limits its role in the diagnosis of IE; transesophageal echocardiography (TEE) is the preferred visual diagnostic modality, with a sensitivity of 80% to 90%, and should be strongly considered in highly suggestive cases even if TTE is negative. Overall, the minor criteria are often used when diagnosing pediatric IE.

### Treatment

The therapy for IE entails a prolonged course of intravenous antibiotics to eradicate the high concentration of organisms deeply embedded within the fibrin-platelet matrix. For a complete review of the suggested regimen of antibiotic therapy, see the American Heart Association recommendations for IE therapy in adults. In brief, duration of intravenous therapy will vary between 2 and 6 weeks depending on bacterial speciation and antimicrobial sensitivity. Blood cultures should be repeated during and after antibiotic therapy to ensure eradication of the offending organism.

### Prognosis

Before the era of antibiotics, IE was universally fatal. Today, however, survival has increased by 70% to 80%. Long-term prognosis is primarily determined by the presence of complications. If treatment is initiated early, then valvar damage, heart failure, embolic events, and heart block can be prevented. However, complete eradication becomes significantly more difficult if the endocarditis involves a prosthetic valve or is caused by a *Staphylococcus* species. In these scenarios, the prognosis is more guarded.

### Prevention

The complications associated with IE along with its difficult management make prevention an integral step in caring for persons at risk. Good oral hygiene and appropriate antibiotic prophylaxis constitute the primary means for achieving this goal. Inappropriate prophylaxis can pose more risk than benefit when considering hypersensitivity reactions to antibiotics. Likely, the best prevention strategy is to maintain good oral hygiene and avoid any unnecessary interventions. The guidelines for IE prophylaxis have

recently been updated, and many conditions previously necessitating prophylaxis have been eliminated. The following are cardiac conditions associated with the highest risk for adverse outcome from IE for which prophylaxis is reasonable: prosthetic cardiac valve or prosthetic material used for cardiac valve repair; history of previous IE, unrepaired CHD including palliative shunts and conduits; completely repaired CHD defects using prosthetic material or a device placed surgically or by catheter-based delivery system (during first 6 months following procedure); repaired CHD with residual defects at the site or adjacent to the site of prosthetic patch or device (which inhibits endothelialization); and cardiac transplant recipients who develop valvulopathy.

### Myocarditis

Myocarditis is a generalized inflammation of the cardiac muscular walls. In a 10-year study of 14,000 cardiac patients cared for at Texas Children's Hospital between 1954 and 1977, 0.5% of patients were diagnosed with myocarditis at presentation and another 2% to 5% at autopsy. Nearly 20% of pediatric sudden deaths may be related to myocarditis. Though its incidence is low in the pediatric population, an accurate and timely diagnosis is critical for improving the related morbidity and mortality. Mortality rates vary inversely with age of onset; nearly 75% of all newborns and infants who develop myocarditis will succumb to the disease. In older children with less fulminant disease, the mortality rate is approximately 25%, with 50% exhibiting a complete recovery and another 25% becoming asymptomatic but having persistent abnormal cardiac function.

### Pathophysiologic Features

Histologically, myocarditis is characterized by viral infiltration of myocytes and the associated immune-mediated cell lysis. Although the enteroviruses, particularly the coxsackievirus B3 and B4 serotypes, are typically reported to be common causative agents, studies using polymerase chain reaction (PCR) amplification have also found adenovirus, and more recently parvovirus, to be regularly associated with myocarditis. The mechanism by which these viruses produce their cellular toxicity is unclear, but an autoimmune response has been suggested by some investigators. Recent evidence shows that these viruses may cause direct damage to the myocardial cells by disrupting sarcomeric linkage proteins, particularly dystrophin, which will interfere with force transduction and result in myocyte dysfunction and heart failure.

### Clinical Manifestations

The clinical presentation in patients with myocarditis can range from mild ECG abnormalities in an otherwise asymptomatic child to fulminant congestive heart failure. Older children will typically have less fulminant presentations, occurring 7 to 10 days after a viral upper respiratory infection or gastroenteritis. Signs and symptoms may include fever, malaise, chest pain, dyspnea, pallor, and poor perfusion. Physical examination may demonstrate muffled heart sounds and a

gallop rhythm, suggesting congestive heart failure. With severe, fulminant onset, cardiogenic shock may be present.

### Evaluation

Laboratory values in a child with myocarditis will be nonspecific and generally consistent with a diffuse inflammatory process. Erythrocyte sedimentation rates, C-reactive protein, and white blood cell and platelet counts may all be elevated. Measures of cardiac cell damage, including troponin-I and creatinine kinase-MB fraction, can be used to establish that myocyte injury has occurred and then to follow these levels to monitor the progress of the condition. Serum viral cultures, serologic titer assays, or PCR amplification of viral genome (or all) may help verify a cause, but an endomyocardial biopsy is required for the definitive diagnosis of myocarditis.

The pathognomonic electrocardiographic finding in myocarditis is decreased precordial voltages consistent with a loss of functioning myocardium (Figure 234-21, A). This finding can generally be differentiated from pericarditis by the absence of diffuse ST segment elevation commonly present in pericarditis. First-, second-, and third-degree atrioventricular block may develop, as well as wide-complex ventricular tachycardias. A chest radiograph often demonstrates global cardiac enlargement and increased pulmonary vascularity with varying degrees of edema (Figure 234-21, B). Two-dimensional echocardiography commonly demonstrates global cardiac chamber enlargement with atrioventricular valve regurgitation and poorly contracting ventricles.

### Treatment

The treatment for myocarditis remains largely supportive. Though antiviral medications, steroids, and intravenous gamma globulin are often administered, limited and somewhat controversial data exist supporting their use. For milder cases, bed rest and hospitalization are sufficient until the child's cardiac status returns to baseline. More severely affected children, however, commonly require

aggressive diuresis, inotropy, chronotropy, afterload-reducing medications, antiarrhythmic agents, ventilator support, and even mechanical circulatory support (ie, extracorporeal membrane oxygenation, ventricular assist devices).

### Management

For children who survive the initial phase but do not fully recover ventricular function or develop chronic heart failure, long-term medical therapy is typically required. Diuresis, afterload reduction, and, in some instances, long-term antiarrhythmic medications (or automatic implantable cardioverter defibrillators [AICDs]) are used. Adult studies examining the use of beta blockers (carvedilol, metoprolol, and bisoprolol) in the setting of heart failure have shown that these agents can reverse abnormal cardiac remodeling, minimize clinical symptoms, and decrease hospitalizations and cardiac-associated deaths. Results from a similar, multicenter, randomized, controlled trial of beta-blocker use in a heterogeneous pediatric population showed no significant outcome benefit with therapy (carvedilol), but there was a trend toward improved ventricular function in the patient subgroup with a morphologic left ventricle. When patients fail to respond adequately to medical or mechanical support, cardiac transplant is the only alternative for long-term survival in appropriately selected patients.

### Pericarditis

Pericarditis is an inflammation of the pericardium and is often associated with effusion (fluid accumulation) within the pericardial sac. However, in conditions such as myxedema (hypothyroidism), patients may have pericardial effusion in the absence of pericarditis. Pericarditis can have both infectious and noninfectious causes. Among infectious agents, the enteroviruses (especially coxsackievirus B), influenza, cytomegalovirus, and Epstein-Barr virus are the most common viral causes, whereas *Staphylococcus aureus*, *Streptococcus pyogenes*, and *Streptococcus pneumoniae* are the most common bacterial pathogens.

**Figure 234-21** A, ECG of a 6-year-old with myocarditis. Note the low QRS voltages throughout limb and precordial leads. Although not seen in every patient with myocarditis, this ECG finding is pathognomonic for this diagnosis. B, Chest radiograph of the same patient who developed myocarditis-induced DCM.

Tuberculous and fungal pericarditis are unusual. Rheumatic fever, autoimmune diseases, postcardiac surgery, uremia, and malignancies such as leukemia are some of the noninfectious causes of pericarditis.

### **Pathophysiologic Features**

Both the parietal and the visceral layers of the pericardium are inflamed, and the pericardial fluid can be serous, serofibrinous, hemorrhagic, or purulent in nature. Myocarditis is often associated with infectious pericarditis, more so with viral than with bacterial agents. However, depending on the virulence of the offending organism, pericarditis can be the more pathologic component of the 2 processes.

The clinical features of pericarditis and the associated effusion are caused by diastolic dysfunction related to abnormal, restricted filling of the heart. Therefore, the symptoms and signs depend on the fluid volume within the pericardial space, the rapidity with which the fluid collects, and myocardial function. A rapid collection of fluid, as occurs in bacterial infections, may cause severe circulatory compromise (cardiac tamponade). A gradually developing pericardial effusion allows the pericardium to stretch, and therefore the increase in the pericardial pressure is slower, which is usually much more readily tolerated. However, if the myocardial function is depressed, then even this gradual increase in pericardial fluid and pressure may cause significant circulatory compromise.

With the onset of cardiac tamponade, the following compensatory mechanisms are activated:

- Tachycardia to improve the cardiac output
- Increase in SVR to raise the falling blood pressure
- Constriction of systemic and pulmonary veins to improve diastolic filling

### **Clinical Manifestations**

A history of viral upper respiratory infection 10 to 14 days before the development of pericarditis is common. Children typically exhibit pain in the left side of the chest, which is worse in the supine position or with deep breathing and relieved on sitting or leaning forward. The pain may radiate to the left shoulder or to the neck.

The child may be febrile, especially with bacterial pericarditis, and may be pale, gray, hypotensive, tachypneic, and tachycardic (signs of low cardiac output). A pericardial friction rub (a biphasic sound) is the cardinal sign of early pericarditis. With further accumulation of pericardial fluid, the friction rub may disappear and the heart sounds may become muffled. In pericardial tamponade, because of the pressure caused by the large amount of pericardial fluid around the heart, the venous return during inspiration is compromised, resulting in a paradoxical rise in the jugular venous pressure (known as the Kussmaul sign) and a decrease in cardiac output and systolic blood pressure (known as pulsus paradoxus). These children will also have other signs of low cardiac output such as pale, clammy skin, gray (sometimes mottled) appearance, dyspnea, and tachycardia.

### **Evaluation**

Chest radiograph may be normal when the pericardial effusion is small. However, with a large effusion, the cardiac silhouette appears enlarged and has a globular appearance. The pulmonary vascular marking may be prominent in patients with tamponade. An ECG may show low-voltage QRS complexes with substantial pericardial effusion; it may also show changes caused by associated myocarditis such as diffuse ST elevation in initial stages. Gradually, the ST segment begins to normalize, with decrease in the T wave amplitude eventually leading to T wave inversion. These ECG changes may resolve completely with the exception of T wave abnormalities, which may persist for long periods.

Echocardiography is most often used to assess the size of a pericardial effusion, which can occur with pericarditis; it is also very useful in detecting evidence for cardiac tamponade and associated conditions (ie, myocarditis).

Computed tomography and magnetic resonance imaging are indicated when the echocardiogram is inconclusive and when pericardial effusion is suspected to be loculated or hemorrhagic. When the pericardial fluid collection is large or rapidly increasing, as in the case of bacterial pericarditis or when tuberculous pericarditis is suspected, performing a diagnostic and therapeutic pericardiocentesis may be necessary. This procedure will drain the fluid to minimize the potential for clinical decompensation from tamponade and allow possible etiologic diagnosis after evaluation of cell count (total and differential), glucose, protein concentration, Gram and acid-fast stain, and appropriate cultures (with viral PCR as indicated) and cytologic assays.

### **Management**

The management of pericarditis depends on the size and etiology of the effusion, as well as its effect on cardiac function. Urgent decompression by percutaneous pericardiocentesis or surgical drainage is life saving in patients with cardiac tamponade. Similarly, urgent drainage is necessary for suspected purulent pericardial effusion. This task can be accomplished with a large-bore pericardial drain or a surgically created pericardial window to permit continuous drainage of purulent material and to prevent development of tamponade. Intrapericardial infusion of a fibrinolytic agent such as streptokinase has been used in patients, including children with purulent pericarditis, and has been shown to decrease the recurrence of pericardial effusion. Appropriate antibiotics should be given intravenously for 4 to 6 weeks. In many cases, after treatment of purulent effusions, a partial or total pericardiectomy will be necessary to prevent the development of constrictive pericarditis related to fibrotic scarring and adhesions within the pericardial space.

The viral form of pericarditis does not require any specific treatment other than a short course of anti-inflammatory medication such as ibuprofen. In children with pericarditis associated with other conditions, such as autoimmune disease and uremia, treatment of the underlying condition leads to the resolution of the

pericardial effusion. Steroids can be considered as a treatment option for persistent or refractory viral or secondary pericarditis.

## CARDIOMYOPATHIES

A cardiomyopathy refers to any structural or functional abnormality of the ventricular myocardium that is not associated with CHD or diseases of the coronary arteries, cardiac valves, or pulmonary vasculature. Four general types of cardiomyopathy exist, and in order of decreasing frequency are dilated, hypertrophic, restrictive, and miscellaneous cardiomyopathies.

### Dilated Cardiomyopathy

Dilated cardiomyopathy (DCM) accounts for 60% to 70% of pediatric cardiomyopathies, with an annual incidence of between 5 and 20 cases per million children. A viral cause is identified in 2% to 15% of cases with biopsy-proven myocarditis; the remaining cases are classified as idiopathic but are likely genetic. Autosomal-dominant, autosomal-recessive, X-linked, and mitochondrial inheritance patterns have been described. Adult studies have shown approximately 20% of patients with DCM have a familial form. Regardless of the cause, the progressive cardiac dysfunction associated with DCM is likely related to the remodeling response of the heart after an inciting injury.

### Pathophysiologic Features

The remodeling cascade consists of the neurohumoral response to inadequate cardiac output. Increased levels of plasma catecholamines, renin, angiotensin II, atrial- and brain-type natriuretic peptides, and overexpression of various cytokine transcripts have been identified in this cascade. Unregulated compensation by these pathways can result in excessive vasoconstriction, intravascular volume expansion, hypertrophy of functioning myocytes, and dilatation of the cardiac chambers. If unchecked, this change in

myocardial structure and function can become irreversible.

### Clinical Manifestations

The clinical presentation of DCM can vary from progressive exercise intolerance with pulmonary congestion to systemic decompensation with cardiovascular collapse. Regardless of severity, diagnosis typically does not occur until the cardiac reserve is exhausted or is nearly exhausted. For this reason, patients with DCM are often diagnosed after an acute viral illness that elevates their resting state metabolism enough to exceed the failing heart's compensatory mechanisms.

In symptomatic patients, the physical examination will be consistent with congestive heart failure. Tachycardia, cachexia, sallow color, and a gallop may be appreciated. Pulmonary congestion will cause tachypnea and, in older children, orthopnea. Progressive ventricular dilatation or infarction of a left-ventricular papillary muscle can cause the early systolic, regurgitant murmur of mitral regurgitation. Hepatomegaly and weakened peripheral pulses may be found with severe cardiac dysfunction. A chest radiograph will generally show cardiomegaly with or without increased pulmonary vascular markings (see Figure 234-21, B). An ECG may show biventricular hypertrophy by voltage criteria with ST segment and T wave abnormalities (Figure 234-22). The echocardiogram will ultimately confirm the diagnosis. Dilated cardiac chambers, atrioventricular valve regurgitation, and depressed systolic function are nearly universal findings for these patients.

### Treatment

Multiple treatment modalities have been implemented to improve left-ventricular systolic function in children with DCM. The primary intervention is pharmacologic and is directed toward treating the symptoms of congestive heart failure and blunting the neurohumoral

**Figure 234-22** ECG of a 2-month-old infant with DCM secondary to the left coronary artery arising anomalously from the pulmonary artery. Note the large QRS voltages in the precordial leads consistent with biventricular hypertrophy and dilatation. The deep Q waves in leads I and aVL are consistent with a lateral myocardial infarction. Inverted T waves in left lateral precordial leads represent a repolarization abnormality and are consistent with left-ventricular strain.

cascade responsible for the pathologic ventricular reverse remodeling. Aggressive diuresis helps reduce pulmonary edema and hepatic congestion when present and helps reduce any excessive intravascular volume expansion. Spironolactone improves outcomes in adults with congestive heart failure by inhibiting part of the neurohumoral axis. Afterload reduction, typically using angiotensin-converting enzyme inhibitors or angiotensin receptor blockers, also decreases morbidity and mortality in this population; its use is discouraged in the acute, decompensated period. The use of beta-blocker therapy, however, is among the few medical interventions for congestive heart failure that has evidence supporting its use in both adults and children. A study by Shaddy et al demonstrated significant improvement in systolic ventricular function after 23 months of beta-blocker therapy in 15 children with DCM and associated congestive heart failure. This class of medication is thought to reverse the maladaptive remodeling effects produced by the excessive catecholamine levels exhibited in these patients. However, results from a multicenter, randomized, controlled trial of beta-blocker (carvedilol) use in a heterogeneous pediatric population showed no significant outcome benefit with therapy, but there was a trend toward improved ventricular function in the patient subgroup with a systemic LV dysfunction. Because this study was somewhat underpowered by a limited enrollment sample, and other smaller series have shown efficacy, many cardiologists continue to use beta blockers as mainstay therapy. Anticoagulation therapy (ie, aspirin, warfarin) is also commonly used to reduce the risk of thrombus formation, which is inherently elevated in the relatively low flow state associated with poor ventricular function and DCM.

Cardiac resynchronization therapy (CRT) is a novel pacing modality used in patients with DCM and heart failure that is refractory to conventional medical management. By decreasing intraventricular conduction delay and the associated uncoordinated muscle contraction, CRT can synchronize ventricular wall motion, improve both diastolic filling and systolic ejection fraction, and, ultimately, reduce patient symptoms. Its use in children is limited by the lack of controlled study data, and more research is needed before CRT can be widely prescribed in this group. In severe cases, ventricular assist devices, extracorporeal membrane oxygenation, or even cardiac transplantation may be indicated in appropriately selected patients if other treatment regimens are unsuccessful.

### **Hypertrophic Cardiomyopathy**

Hypertrophic cardiomyopathy (HCM) is the second most common form of cardiomyopathy (20% to 30%) in children, with an annual incidence ranging between 4 and 6 per 1,000,000. Autosomal-dominant, autosomal-recessive, and mitochondrial inheritance patterns have been described, with approximately 100 mutations mapped to at least 13 different cytoskeletal or sarcomeric genes. Multiple familial forms of HCM exist, with nearly 40% to 50% demonstrating a point mutation on chromosome 14q1 (β-myosin heavy chain). HCM has also been shown to occur in

association with both Noonan syndrome and Friedrich ataxia.

### **Pathophysiologic Features**

HCM is characterized by wall hypertrophy of all 4 heart chambers but most notably of the IVS and left-ventricular posterior wall. Hypertrophy may be concentric (50%) or asymmetric. If the IVS is disproportionately thickened, then left-ventricular outflow tract obstruction (LVOTO) can ensue in 30% of cases. Furthermore, when hypertrophy is severe, flow through the intramural coronary arteries may be decreased or even occluded, resulting in myocardial ischemia. The primary abnormality associated with HCM is diastolic dysfunction of the left ventricle, which often produces progressive exercise intolerance. In the absence of LVOTO, worsening diastolic dysfunction is sufficient to produce this symptom. When severe IVS thickening does occur, the increased left-ventricular outflow gradient experienced during exercise results in performance and duration limitations.

### **Clinical Manifestations**

The clinical presentation of patients with HCM varies, from infants with congestive heart failure to asymptomatic children with or without a heart murmur. Although the classic presentation is that of a syncopal patient with a loud cardiac murmur, this is rarely the case. More often, a routine examination will demonstrate a harsh systolic ejection murmur at the left sternal border with radiation to the neck. If present, this murmur of LVOTO is then accentuated when a squatting patient is asked to stand, decreasing the SVR and increasing the gradient across the LVOT. The remainder of the physical examination is typically normal. Obtaining a family history is critical because nearly one-half of all patients with HCM will have a first-degree relative with the diagnosis or with a history of syncope or sudden death.

### **Evaluation**

The ECG is abnormal in 90% to 95% of children with HCM, with large voltages in the precordial leads, suggesting biventricular hypertrophy, either ST segment elevation or depression, T wave inversion, and abnormally deep Q waves. The delta wave of Wolff-Parkinson-White syndrome is occasionally noted in association with HCM. Although LVOTO is often considered the source of morbidity and mortality for these children, ischemia-induced arrhythmias are much more likely. This finding is suggested by both the relatively low prevalence of LVOTO in patients with HCM (20% to 30%) and the tendency for frequent episodes of ventricular tachycardia and ST segment elevation on ECG during exercise. Importantly, sudden death (usually from ventricular fibrillation) is the most common cause of death in undiagnosed adolescents and young adults.

Echocardiography is the method of choice for diagnosis of HCM. Attention should be focused on the type of hypertrophy (concentric vs asymmetric), ratio of IVS to left-ventricular posterior wall thickness ( $>1.5$  is diagnostic), presence of LVOT or RVOT obstruction, and systolic anterior motion (SAM) of the anterior

mitral valve leaflet. Historically, SAM is thought to be caused by the Venturi effect of fluid movement in which turbulent blood flow through the ventricular outflow tract produces a pressure gradient, pulling the anterior mitral leaflet into the ventricular outflow tract, resulting in mitral regurgitation. Recent data have suggested that mid-cavitary obstruction common in HCM causes *drag* forces that may also contribute to SAM.

### Treatment

Once diagnosed, the primary focus of treatment for the child with HCM is providing symptomatic relief and minimizing the risk of lethal arrhythmias. Pharmacologic intervention is indicated for children who have symptoms or LVOTO at rest. First-line therapy for these patients is usually beta blockers. Though its mechanism of action is unclear, beta blockade reduces heart rate and myocardial oxygen demand, allows for increased diastolic filling time, and may have some inherent antiarrhythmic properties. Furthermore, by decreasing heart rate and increasing the diastolic filling period, a larger stroke volume will be produced per heartbeat and may minimize the severity of LVOTO. If beta blockers are poorly tolerated, then calcium channel blockers have been shown to produce similar effects. In addition, patients will generally be asked to participate in exercise stress tests and have 24-hour Holter monitoring to help stratify their risk for ventricular tachycardia and sudden death. The presence of asymptomatic, nonsustained ventricular tachycardia on Holter monitor has been shown to increase the risk of sudden death 8 to 10 times compared with HCM patients without this anomaly; the overall risk of sudden death in patients with HCM is 1% to 2% per year (may be as high as 4%–5% in adolescents). When tachycardia is present, most experts recommend the antiarrhythmic medication amiodarone as the drug of choice or an AICD implantation (or both) for the treatment of malignant ventricular ectopy in this patient population. Prophylactic implantation of AICDs is being studied and has been strongly recommended under the following conditions: left ventricle wall thickness greater than 3.0 cm, family history of death related to HCM, unexplained syncope, and nonsustained ventricular tachycardia on Holter monitor. AICD placement as secondary prevention (in patients with aborted sudden death or documented ventricular tachycardia or fibrillation) is now considered standard of care.

In patients with HCM whose symptoms are related to their degree of LVOTO, reduction of flow gradient is recommended. The Brock or Morrow procedure is a surgical myomectomy reserved for symptomatic, medically refractory patients with a ventricular outflow tract gradient of more than 50 to 60 mm Hg. Although the 10-year survival rate after this procedure is approximately 86%, the intraoperative mortality rate can approach 5%. Medical septal reduction is an alternative method of improving LVOTO by infusing desiccated alcohol into the septal perforating coronary vessels within the IVS using TEE guidance in the cardiac catheterization laboratory. As with surgical myomectomy, this procedure has been advocated

for patients with HCM who are failing medical management and has been used with a resting ventricular outflow tract gradient as low as 40 mm Hg. It reduces the morbidity and mortality related to surgery, but even in experienced centers, an increased risk exists of coronary artery dissection, uncontrolled myocardial infarction, and a 5% to 10% risk of complete heart block requiring pacemaker placement.

### Restrictive Cardiomyopathy

Restrictive cardiomyopathy (RCM) is the rarest form of cardiomyopathy in children. It is characterized by a loss of ventricular compliance with a subsequent increase in end-diastolic filling pressures. Systolic ventricular function is preserved, but diastolic relaxation is compromised. The cause of RCM is unknown but is thought to be associated with both genetic (ie, mutations in the desmin, troponin I, transthyretin I $\beta$  genes) and nongenetic causes (sarcoid or amyloidosis, which are common causes in adult patients but reportable in pediatric cases). Care must be taken to distinguish RCM from constrictive pericarditis using echocardiogram, catheterization, magnetic resonance imaging studies, or any combination of these measures. Diagnosis is made via echocardiography, which shows normal ventricular size and function associated with dilated atria caused by the ventricular diastolic dysfunction. Elevated left-ventricle end-diastolic pressures can ultimately result in pulmonary hypertension and pulmonary vascular disease, which is one of the most common and severe complications of RCM. This form of cardiomyopathy is typically nonresponsive to conventional pharmacologic therapy, but anticoagulation is indicated since the risk of intracavitary thrombosis and stroke is increased in these patients. Transplant is the only known definitive therapy. Unfortunately, owing to its usual late diagnosis, pulmonary hypertension that is unresponsive to pulmonary vasodilators is the most commonly cited problem preventing heart transplantation in these patients. Without transplant prognosis is poor, with death occurring within 1 to 4 years of diagnosis (in symptomatic patients, usually from pulmonary hypertensive crises or sudden death). Therefore, such patients should be referred for heart transplantation once the diagnosis is made.

### Miscellaneous Cardiomyopathies

Arrhythmogenic right-ventricular dysplasia (ARVD) and mitochondrial and noncompaction cardiomyopathies comprise only 2% to 3% of pediatric cardiomyopathies. Dysplasia of the right ventricle in patients with ARVD develops from fatty deposits within the ventricular walls. As a result, these patients are at risk for life-threatening ventricular tachycardias, particularly in affected individuals younger than 30 years of age. Diagnosis of ARVD is typically made from dysrhythmias, echocardiogram, or magnetic resonance imaging. Treatment is directed at preventing life-threatening arrhythmias through the use of both medications and AICDs. Patients with mitochondrial cardiomyopathies often exhibit the condition early in life with a hypertrophied or, less commonly, dilated, poorly functioning

heart. In general, this maternally inherited disorder can be variably associated with other muscle, liver, neurologic, and developmental abnormalities.

Last, left-ventricular noncompaction cardiomyopathy (LVNC) is characterized by deep crevices or trabeculations within the normally smooth-walled left ventricle, which reduces cardiac function. The cardiac dysfunction associated with LVNC has been demonstrated to have a varying age of onset, from the newborn period to adulthood. This cardiomyopathy may also be associated with other mitochondrial, metabolic, and systemic (Barth syndrome) disorders.

## CARDIAC TRANSPLANTATION

Orthotopic heart transplantation (HTx) has become a standard therapy for treating both end-stage congenital and acquired heart disease. Although the indications for HTx are similar across the pediatric population, the frequency of each indication changes with age. More than 75% of all recipients younger than 1 year of age undergo HTx because of surgically irreparable CHD; this comprises only approximately 25% of the 11- to 17-year-old HTx recipients. Conversely, cardiomyopathy-related heart failure and dysrhythmias that are unresponsive to medical therapy result in HTx in 17% and 62% of the infant and adolescent population, respectively.

Once HTx is indicated, an extensive evaluation is necessary to determine its feasibility. Cardiac catheterization is required to determine both hemodynamics and PVR. Significantly elevated PVR or elevated PVR that is unresponsive to vasodilatory therapy (ie, oxygen and nitric oxide) can preclude HTx candidacy, whereas active malignancy and hepatic cirrhosis are absolute contraindications. The presence of bacterial or viral infection is a relative contraindication, and the decision to proceed with HTx should be made based on the individual patient's clinical status. A complete antiviral antibody titer panel (for herpes simplex virus, cytomegalovirus, HIV, Epstein-Barr virus, and hepatitis A, B, and C) should be obtained to rule out infection and to help guide the use of antiviral medications in the immediate postoperative period. Panel reactive antibody testing is necessary to assess the amount of circulating preformed human leukocyte antigen antibodies in the recipient's serum, which may limit acceptable donor organs or cause hyperacute rejection in the recipient if the donor has antigens to which the recipient has already made antibodies. Finally, both social and financial screening evaluates a potential recipient's emotional coping skills and verifies that the financial burden of the transplant is minimized.

Transplant status classification is the next critical step and strongly influences the expected waiting time. Potential recipients listed as UNOS (United Network for Organ Sharing) status 1a will generally wait several days to months before receiving a heart transplant, assuming survival is possible for this period. This classification, however, requires a patient to be inotrope dependent and hospitalized. Depending on weight and blood type, infants older than 6 months listed as status 2 can expect to wait up to several months; and adolescent children may require as long

as 2 years before a suitable heart is located. Transplant status can change at any time if the clinical condition improves or worsens.

A thorough discussion of the surgical procedure involved in HTx is beyond the scope of this text. Briefly, the donor heart is harvested in its entirety, with the exception of a cuff of posterior left atrial wall, which contains the pulmonary veins. Once the recipient is placed on cardiopulmonary bypass, the heart is removed in a reciprocal fashion. Anastomosis of the donor heart to the recipient is performed by either a biatrial or, more commonly, a bicaval (SVC-IVC) connection. The postoperative period for HTx recipients poses the unique challenge of managing a patient with a denervated heart that has been ischemic for as long as 4 hours. Without the sympathetic and parasympathetic nerve fibers innervating the sinoatrial and atrioventricular nodes, the resulting heart rate is entirely dependent on the intrinsic sinoatrial nodal rate. Neither Valsalva nor carotid massages will influence heart rate; atropine, the cholinergic receptor antagonist, is also ineffective. Although the resting heart rate of a transplanted heart is typically higher than normal controls, it is often abnormally slow in the immediate postoperative period because of sinoatrial node ischemia related to harvest and transplantation. Therefore, chronotropy can be provided by the selective  $\beta_1$  agonist isoproterenol and titrated to produce the desired heart rate. As the transplanted heart begins to recuperate from the surgical insult, heart rate and cardiac output will increase to meet the patient's needs.

Immunosuppressive medications are typically started soon after the transplantation is complete. Most HTx recipients receive a regimen that includes a calcineurin inhibitor (ie, tacrolimus or cyclosporine), an antimetabolite (ie, mycophenolate mofetil or azathioprine), and corticosteroids. Corticosteroids are generally weaned within the first few post-HTx months, so long as no treatable rejection is detected. These medications all carry a significant side effect profile that often directs dosing and choice of medication. Both cyclosporine and tacrolimus are associated with hypertension, nephrotoxicity, and derangement of the lipid profile. These adverse effects are more common with cyclosporine than with tacrolimus. Tacrolimus and cyclosporine drug levels are monitored, with the therapeutic target levels gradually decreasing with time post-transplant. Azathioprine also necessitates frequent blood monitoring because of its adverse effects of neutropenia and hepatotoxicity. Mycophenolate is known to produce lymphopenia and gastrointestinal distress and may require dose adjustments accordingly. Side effects of corticosteroids have been well described.

The immunosuppressed state in which these patients live increases the risk of several potential complications. During the early phase of immunosuppression and the subsequent 6 months, patients are at the highest risk for bacterial and opportunistic infections, occurring in 52% and 15% of HTx recipients, respectively. After 6 months, the predominant infectious organisms shift from bacterial to viral (83% of infections), and the specific microbes parallel those afflicting the general, nonimmunosuppressed pediatric

population (ie, cytomegalovirus, Epstein-Barr virus, adenovirus, enterovirus, influenza) as the immunosuppression medications are decreased to maintenance dosing. For patients still requiring routine immunizations, live viral vaccines (ie, oral poliovirus, measles-mumps-rubella, varicella, live attenuated influenza [FluMist], rotavirus) should not be given because of the risk of active infection. Furthermore, the immunosuppressed patient's response to vaccinations will be blunted, particularly during the early post-HTx period, and any systemic antigenic response may precipitate a rejection episode. Therefore, all nonlive vaccinations should be given approximately 3 months post-transplant to minimize rejection.

Although excess immunosuppression predisposes these patients to serious infectious complications, deficiency in these medications places them at significant risk for rejection. This potentially life-threatening situation occurs when immunosuppression is unable to prevent the recipient's body from recognizing and attacking the donor heart's nonself antigens. Cellular rejection is the most common subtype and is a T cell-mediated injury that can begin within the first 5 to 7 days post-transplant, with the highest incidence during the first 3 post-transplant months. Patients may exhibit complaints of malaise, anorexia, gastrointestinal distress, low-grade fever, or nonspecific changes in sleeping patterns. If significant rejection is present, then physical examination will reveal hepatomegaly, a mild elevation in heart rate from baseline, and, possibly, a new murmur or gallop. These patients require prompt evaluation and assessment, which will likely include an echocardiogram to assess cardiac function and, if indicated, an endomyocardial biopsy. If disease proves the presence of rejection, then pulse steroids are administered, and the maintenance immunosuppressive regimen will usually be augmented. Repeat biopsy is necessary to verify effective treatment for the rejection episode, and any interventions (ie, scheduled vaccinations) that might upregulate the immune response should be delayed for approximately 3 months after resolution of the episode.

As pediatric heart transplantation has become increasingly successful, the medical community is learning more about the associated long-term complications. Post-transplant lymphoproliferative disease is an abnormal growth of lymphoreticular cells in immunosuppressed patients and has been linked to primary post-transplant Epstein-Barr virus infection. It occurs in approximately 5% to 10% of pediatric HTx recipients. Some patients will respond to a decrease in immunosuppression, while others will require chemotherapy and possibly even surgical resection. The other significant long-term complication is post-transplant coronary vasculopathy (TCAV). This condition is described as a progressive intimal and medial thickening of the transplanted heart's coronary arteries, with loss of coronary flow reserve and eventual luminal obliteration. The risk of TCAV increases with each episode of rejection (particularly after the first year), certain infections (ie, cytomegalovirus), original harvest time, and associated donor ischemic time; it is also increased in the presence of abnormal lipid profiles.

**Figure 234-23** Kaplan Meier survival curve for 5,677 pediatric patients after orthotopic heart transplant. (From Boucek MM, Edwards LB, Keck BM, et al. *Registry of the International Society for Heart and Lung Transplantation: 8th official pediatric report-2005*. J Heart Lung Transplant. 2005;24(8):968-982, with permission. Copyright © 2005, Elsevier.)

Because of their ability to lower the cholesterol-low-density lipoprotein fraction and their antioxidant/antiproliferative properties, many physicians are recommending statins (ie, pravastatin, atorvastatin) in their transplant recipients. Freedom from TCAV decreases with time from transplant and with each decade of life after which the transplant occurs. Although newer immunosuppressant agents (ie, sirolimus) have shown initial promise as potential treatments for TCAV, retransplantation is currently the only definitive therapy.

Actuarial survival curves currently demonstrate an overall 50% survival at 13 years post-transplant (Figure 234-23). Younger age at transplant is associated with longer survival and decreased need for retransplant. Although transplantation is a formidable treatment strategy for most children and their parents, approximately 90% of HTx recipients surveyed at 1, 3, and 5 years post-transplant report excellent quality of life with no activity limitations. Transplantation seems to be an acceptable end point for patients with irreparable congenital or acquired heart disease but continues to be limited by the number of available donor hearts; approximately 20% to 30% of all patients die while awaiting a suitable donor. Additional research investigating novel immunosuppression or alternative biologic cardiac replacement strategies may help change the fate of these end-stage patients.

## WHEN TO CONSULT A PEDIATRIC CARDIOLOGIST

The question of when to refer a newborn to a pediatric cardiologist can be difficult. This issue is further complicated when practicing in rural areas where a *consult* may mean transport to another hospital or discharge home with the uncertainty of a family keeping their appointment with the pediatric cardiologist. Although some clinical findings can be pathognomonic for a cardiac anomaly, many lesions have only subtle clinical findings. The astute physician is one who can identify *abnormal* from the myriad of patients they encounter in a day. The pediatric cardiologist is

continuously indebted to the general pediatrician's ability to perform this function. Likely, one of the most stressful parts of a pediatrician's practice is determining when a newborn's cardiac murmur is pathologic (see Chapter 101, The Newborn With a Heart Murmur or Cyanosis). Diminished or absent femoral pulses are never normal and should always be evaluated by a pediatric cardiologist. The transition from normal fetal circulation to normal postnatal circulation can produce a variety of cardiac murmurs; distinguishing physiologic from pathologic requires patience and experience.

A PDA is classically described as producing a *machinery* murmur because of its continuous, undulating character. The murmur is appreciated during both systole and diastole because both systolic and diastolic pressures are higher in the aorta than in the pulmonary arteries. Therefore, blood is continuously shunting from the aorta to the pulmonary artery (left to right). As the ductus arteriosus begins to close, the pressure gradient across this vascular conduit increases, making the murmur higher in pitch, but may result in loss of the diastolic component. The ductus arteriosus arises from the proximal portion of the left pulmonary artery and generally inserts into the aorta distal to the left subclavian artery. This anatomic feature results in the murmur being best auscultated in the left, upper sternal border of the chest and may radiate to both lung fields. A pediatric cardiology consult is warranted if this murmur exists in the presence of decreased renal perfusion or pulmonary overcirculation because medical or surgical closure may be indicated. Otherwise, in a healthy infant, outpatient follow-up is recommended. Generally, PDAs close within days to months postnatally. PDAs persisting beyond the young infant period can usually be closed by coil occlusion in the catheterization laboratory.

Similar to a PDA, the systolic murmur produced by coarctation of the aorta will also be loudest at the left upper sternal border. Unlike a PDA, however, a coarctation murmur will generally radiate to the back, medial to the left scapula. In this scenario, palpable femoral artery pulses must be verified, and upper and lower extremity blood pressures must be obtained to assess for a blood pressure gradient. If pulses are absent or thready, or if lower extremity blood pressures are more than 15 mm Hg less than upper extremities, then a pediatric cardiology consult should be obtained immediately (see previous section on coarctation of aorta).

Peripheral pulmonary branch stenosis, which is accompanied by a physiologic murmur, does not require urgent consultation. A short, relatively high-pitched II/VI systolic ejection murmur that is auscultated equally on both sides of the sternum with diffuse radiation to both lung fields is characteristic of this natural transition period from fetal to postnatal circulation. The fact that this natural state has been declared a *diagnosis* is unfortunate because it results in undue angst for both physicians and families. Most physicians are concerned they may be missing the murmur produced by pulmonary stenosis. This murmur is distinct from that of peripheral pulmonary stenosis in both its severity and focality. A murmur produced by

significant valvar pulmonary stenosis will be harsh in character, at least grade III on a severity scale of I to VI (see Table 234-1) and is often preceded by a valve click. It will be best auscultated at the left sternal border but will radiate to both lung fields. Conversely, peripheral pulmonary branch stenosis will be a softer, less intense murmur that is equally audible throughout the chest.

Another common scenario the pediatrician faces is the newborn with Down syndrome. Estimates suggest that nearly 40% to 60% of these children are born with some form of CHD and comprise approximately 9% of the pediatric cardiologist's practice. The AVSD is the most common defect in these patients, occurring in approximately 60%, with nearly 70% of all patients with AVSD having trisomy 21. As discussed in the section on left-to-right shunting lesions, these lesions may not produce an audible murmur until PVR decreases significantly. However, because neither lesion is typically fatal in the first several weeks of life, discharging them from the hospital before seeing a pediatric cardiologist is reasonable if the patient is otherwise stable and acyanotic. Of note, the AVSD is one of the defects that can be suspected with ECG. The normal newborn ECG will meet voltage criteria for right-ventricular hypertrophy and have a concomitant right axis. The AVSD, however, will demonstrate a left axis deviation and a small Q wave in lead aVL (see Figure 234-9, B). Regardless of their immediate postnatal course, all patients with Down syndrome should be evaluated by a pediatric cardiologist within the first month of life.

Last is the issue of managing the cyanotic newborn. In most of these situations, a cardiac lesion is not the cause. This notion is supported by the fact that only 5 to 8 of 1,000 live births are affected by a congenital heart lesion, and a significantly smaller number of those are cyanotic heart lesions. Pulmonary disease is more commonly the culprit. Nevertheless, the general physician can take several steps to help elucidate an etiology.

First, the physician must verify that cyanosis is truly present. Acrocyanosis is a common occurrence in newborns, particularly in the setting of volume depletion or cool extremities. The  $\text{SaO}_2$  should be obtained on a warm, well-perfused, calm infant on both upper and at least 1 lower extremity. If this setting is difficult to attain, then ear lobe  $\text{SaO}_2$  offers an alternative. Once obtained, if saturations remain lower than approximately 92%, then a difference in saturation between upper and lower extremities should be evaluated. Although rare, *paradoxical cyanosis*, or lower  $\text{SaO}_2$  in the upper extremities than lower extremities, occurs in d-TGA with persistent fetal circulation. Lower-extremity cyanosis alone can occur with pulmonary hypertension, severe coarctation of the aorta, and critical aortic stenosis. Right-to-left shunting of oxygen-poor blood through a ductus arteriosus into the descending aorta is the etiology of the asymmetric cyanosis in these settings. Full-body cyanosis can occur in a number of scenarios, including respiratory distress syndrome, any of the cardiac lesions categorized as *right-to-left shunting lesions*, d-TGA

(without persistent fetal circulation), or complete mixing lesions.

Paradoxically, these same lesions can produce  $\text{SaO}_2$  levels of more than 92% in the newborn period. This discrepancy can be produced by the high oxygen affinity of fetal hemoglobin. Therefore, if a cyanotic heart lesion is suspected, then obtaining arterial  $\text{PaO}_2$  values is mandatory. A hypoxemic  $\text{PaO}_2$  of 60 mm Hg produces an  $\text{SaO}_2$  of more than 90%, which alone might falsely reassure the physician. Persistent hypoxemia (<70–80 mm Hg) despite adequate oxygen therapy should increase the level of suspicion for a CHD. Failure of the *hyperoxia* challenge is often sufficient evidence for evaluation by a pediatric cardiologist and arguably for commencement of a prostaglandin E1 infusion.

This medical intervention constitutes a critical step in the management of a patient with suspected cyanotic heart disease. With the exception of the significant side effects associated with prostaglandin E1 infusion and its use in the setting of obstructed TAPVR, generally no physiologic scenario is worsened by this medication. Apnea, irritability, hyperthermia, jitteriness, and, possibly, decreased white blood cell function are the recognized complications. The major concession the physician must make is accepting the high probability of intubation, which is often already required for patient stability. Prophylaxis with caffeine or aminophylline may decrease the risk of prostaglandin E1-associated apnea. Prostaglandin E1 dosing ranges from 0.01 to 0.2 mcg/kg/min. As with most medications, higher doses inherently increase the side effect profile. Notably, the PDA diameter cannot generally be titrated by changing infusion doses. Once open, only doses of 0.01 to 0.02 mcg/kg/min are usually required to maintain patency.

Before or concurrent with the previously mentioned interventions, a chest radiograph and ECG should be performed. The former can help evaluate pulmonary vasculature and size of the cardiac silhouette. Cyanosis can occur in the presence of diffusely increased pulmonary vascular markings (ie, pulmonary etiology, cardiac disease with pulmonary edema) or near absence of pulmonary vascular markings (ie, cardiac lesion with inadequate pulmonary blood flow). The cardiac silhouette is generally only helpful when extreme cardiomegaly exists, as with severe Ebstein anomaly. The classic descriptions of a *boot-shaped heart* (ie, tetralogy of Fallot) or *egg on a string* (ie, d-TGA) are often overdiagnosed on chest radiographs because of the relative right-ventricular hypertrophy and mesocardia seen in many normal newborns. The newborn's ECG can help suggest the diagnosis of AVSDs (northwest QRS axis), hypoplastic left or right ventricles (decreased voltage in left or right precordial leads, respectively, and abnormal QRS axes), and Ebstein anomaly (right atrial enlargement) (Figure 234-24).

The pediatric cardiologist's echocardiogram can confirm a suggested diagnosis in most situations. Cardiac catheterization is required in a limited number of lesions to verify anatomy or for atrial septostomy if the existing ASD is inadequate (ie, d-TGA,

single-ventricle hearts with atrioventricular valve stenosis or atresia).

The remaining management decisions entail determining whether surgical intervention is required and maintaining cardiovascular stability until that time. As described in the previous section on Complete Mixing Lesions, the major concerns during the preoperative period are end-organ perfusion and oxygen delivery. Proper preoperative management maximizes survival and minimizes morbidity and mortality. This goal is best achieved through an integrated approach involving nurses, allied health team members, family members, and physicians. Available information regarding diagnosis, prognosis, and possible morbidities should be freely exchanged to enable an informed and realistic outlook for all persons involved.

In contrast to patients needing surgical intervention, children with several of the acquired heart diseases can be primarily managed by their general pediatrician. Kawasaki disease can generally be diagnosed and treated before a pediatric cardiologist is ever consulted. An echocardiogram is needed to evaluate for coronary artery aneurysms and, in some cases, to confirm the diagnosis of atypical Kawasaki disease. However, in the absence of cardiac involvement at either presentation or a 2- to 4-week follow-up appointment, further evaluation by a pediatric cardiologist is probably unnecessary. IE is another example of heart disease that the pediatrician can both diagnose and manage with limited involvement of a pediatric cardiologist. Multiple positive blood cultures demonstrating the same organism constitute the most accurate method for diagnosing IE. The low sensitivity of TTE for septic, valvar vegetations decreases its effectiveness in the diagnosis of IE. If IE is strongly suspected, then the more sensitive TEE can be performed if repeated TTEs have been negative. However, all types of CHD (ie, bicuspid aortic valve, VSD) must be ruled out and an adequate history of central venous catheters must be obtained to determine an etiology. Once the patient has received adequate therapy and demonstrated several negative blood cultures, the infection can generally be considered *cleared*. If no evidence exists of CHD or significant valvar derangement, then continued evaluation by a pediatric cardiologist may not be indicated. Last, patients diagnosed with rheumatic carditis should continue to be treated aggressively for all episodes of streptococcal pharyngitis and receive appropriate procedural antibiotic prophylaxis.

The patient with cardiomyopathy typically requires long-term involvement of a pediatric cardiologist. During the first 3 or 4 years of life, however, these patients will see their general pediatrician more frequently, making this relationship crucial for the recognition of progressive disease. Weight loss or a plateau in weight gain, missed developmental milestones, fatigue, activity intolerance, or personality changes can all be subtle indicators of declining cardiac function. In the presence of a murmur, new gallop, or abnormal ECG or chest radiograph, evaluation by a pediatric cardiologist is indicated.

**Figure 234-24** A, ECG of a newborn with HLHS. Note the left-axis deviation of the QRS vector and the paucity of left-ventricular QRS forces in the precordial leads. B, ECG of a newborn with Ebstein anomaly of the tricuspid valve. Note the peaked P waves in leads II and V1 consistent with severe right atrial enlargement.

Heart transplant recipients present another complicated situation for the general pediatrician. Their immunosuppressed status is typically the source of much concern and confusion. A febrile, immunosuppressed heart transplant recipient warrants a thorough evaluation, and, if an obvious, treatable etiology cannot be identified (ie, otitis media, viral upper respiratory infection), then their transplant cardiologist should be involved in the evaluation to minimize the chance that graft rejection will be misinterpreted as a common, benign infectious illness. New-onset fatigue, shortness of breath, exercise intolerance, low-grade fever, vomiting, or diarrhea may all be signs of rejection and require the expertise of the transplant cardiologist. Unexplained abdominal distention, pain, or vomiting should prompt evaluation for an ileus or intussusception because post-transplant lymphoproliferative disease can produce these symptoms; abdominal pain may also be a sign of intestinal angina caused by decreased cardiac output. Because the transplanted heart is denervated, C-fibers, which relay anginal-type chest pain to the brain, have been cut, and the absence of chest pain should not be comforting to the physician. Furthermore, the denervated, transplanted heart will not become significantly tachycardic in response to fever or pain. Therefore, baseline heart rates in

these patients become critical information for the physician, given that an increase of only 10 beats per minute may indicate imminent cardiovascular collapse. The previously mentioned scenarios are intentionally broad and nonspecific; they are intended to demonstrate the subtle clinical changes that may be harbingers of serious illness and to provide guidelines for the pediatrician to consider consultation with a pediatric transplant cardiologist.

Finally, for the previously mentioned cardiac diseases, an important point to note is that the recommendations regarding physical activity and sports participation in patients with CHD vary significantly. The subject of exercise intensity, duration, or participation in any type of athletic event should be discussed with the health care team (including cardiologist and pediatrician), with the patient, and with the patient's family to ensure that no unnecessary or unknown risks are taken.

## Chapter 235

# CONTACT DERMATITIS

Jonette E. Keri, MD, PhD; Linda S. Nield, MD

As the name implies, contact dermatitis is inflammation of the skin secondary to contact with an offending agent. Two broad types of contact dermatitis include *irritant contact dermatitis* and *allergic contact dermatitis*. The clinical presentation and treatment of these 2 entities are similar.

**ETIOLOGY****Irritant Contact Dermatitis**

Irritant contact dermatitis is the result of skin exposure to substances that cause an inflammatory reaction that is not immune mediated. An array of irritant agents may be present in the home, child care center, or school, and may include harsh detergents and cleaning materials. Parents or pediatricians may be aware immediately of the offending agent or may use a diary to chart symptoms and associated activities

and exposures. If the irritant dermatitis is acute, then identifying the culprit is often easy, given that it may be only a single agent. In chronic cases, multiple offenders are often present. If a child has repeated episodes of irritant contact dermatitis that compromise the protective skin barrier, then a fertile environment for subsequent allergic contact dermatitis may result.

Diaper dermatitis is a common irritant dermatitis in children. Urine, feces, and persistent moisture macerate the occluded skin of the perineum. Of note, typical irritant diaper dermatitis does not involve the creases of the infant's skin. If the femoral creases or anal area are involved, then the infection is likely to be candidal. Candidiasis produces red, often macerated plaques accompanied by satellite papules or pustules. Diaper rash that persists longer than 3 days is likely secondarily infected with yeast. (See Chapter 242, Diaper Rash.)

Irritant contact dermatitis caused by airborne agents (dust or volatile chemicals) is often missed and must be considered in all cases. Solvent sniffers, typically preteens and young adolescents who inhale aerosols to alter mental status, are susceptible to irritant contact dermatitis secondary to the airborne agent. These patients may have irritant dermatitis of the arms and chest, along with the eczematous changes found mostly around the nose and mouth.

**Allergic Contact Dermatitis**

Allergic contact dermatitis is immune mediated and is a type IV delayed hypersensitivity reaction. Such reactions require prior exposure to the allergen to produce the event of dermatitis. Delayed hypersensitivity reactions are caused by primed T cells, producing a cascade of cytokines and chemotactic factors leading to dermatitis.

As with irritant dermatitis, an initial episode of allergic contact dermatitis may be easily identified because the rash usually is localized to a specific area, and the history of the offending agent can be ascertained. Poison ivy and nickel are very common causes of allergic reactions.

Commonly, poison ivy is given as an example when allergic contact dermatitis is described; it represents *Toxicodendron* (Rhus) dermatitis. This plant, along with poison oak, poison sumac, Japanese lacquer tree, the cashew nut tree (allergen in the nutshell), mango (allergen in rind, leaves, or sap), Rengas tree, and Indian marking nut tree, are members of the Anacardiaceae family of plants. The dermatitis that these plants trigger appears within 48 hours of exposure in a previously sensitized individual, often producing linear arrays of vesicles where the offending plant has come in contact with the skin. Another common site in young boys includes the genitals because, in many cases, they transfer the allergen to this area when voiding.

An allergic reaction to nickel is common and remains the most frequently positive patch test allergen in North America. With the increased incidence of body piercing in the pediatric population, allergic reaction must be considered when an area at a piercing site is red, scaling, and irritated (Figure 235-1). Nickel is also located on areas of clothing such as the snaps and zippers on trousers or blouses (Figure 235-2), and it has even been detected in electronics.

**Figure 235-1** Nickel contact dermatitis at the site of an earring.

Other allergens becoming more important include topical antibiotic preparations, such as those containing neomycin, which have shown a notable increase in positive patch test reactions since the 1970s; hair dye products that contain paraphenylenediamine; and latex in children who have repeated exposure to it in clinical settings. Most recently, methylisothiazolinone (MI) has shown up as an evolving allergen in the pediatric population. This allergen is found in skin and hair products and functions as a preservative. It is important to note that MI is commonly found in products marketed as “sensitive,” “gentle,” “organic,” or “hypoallergenic,” and it is often a component of cleansing wipes. Thus, in recalcitrant dermatitis of the mouth, hands or genital/anal regions, use of products containing MI should be investigated.

### EPIDEMIOLOGIC CONSIDERATIONS

Contact dermatitis affects both genders, all ages, and all races. Differences among individuals pertain mostly to habits of exposure. In addition, regional differences can exist, depending on the allergens or irritants in the environment. Contact dermatitis represents 6% to 10% of visits to dermatologists' offices, and about 10% of dermatology consultations for hospitalized pediatric patients.

Irritant contact dermatitis is seen more commonly than allergic contact dermatitis in very young children because they lack the repeated exposure needed for allergic contact dermatitis to develop. However, some experts suggest that allergic contact dermatitis may account for at least 20% of all childhood dermatitis.

### DIFFERENTIAL DIAGNOSIS

The differential diagnoses for contact dermatitides include atopic dermatitis, seborrheic dermatitis, tinea, and psoriasis. Rare conditions, such as acrodermatitis enteropathica from zinc deficiency or Letterer-Siwe disease, a serious disorder of histiocytes, can mimic diaper dermatitis and must be considered.

**Figure 235-2** Contact dermatitis caused by nickel in a clothing snap or belt buckle affecting the lower abdomen.

### CLINICAL MANIFESTATIONS

The clinical presentation of both types of contact dermatitis can be similar. Allergens and irritants can produce a range of responses from eczematous changes of the skin noted by pink, scaling, irritated plaques to severe vesiculobullous eruptions characterized by blistering changes of the skin and severe pruritus.

Irritant contact dermatitis can lead to lichenification, which is characterized by accentuation of skin lines, often with hyperpigmentation, and an almost hardening of the skin. Acute irritant dermatitis can occur within minutes to hours after exposure. The intensity of the reaction is related to the nature of the chemical, the concentration, and the duration of contact. Conditions that foster a more severe reaction include wet skin and skin under friction, occlusion, or pressure. In addition, patients with a history of atopic dermatitis are likely to experience contact dermatitis.

Allergic contact dermatitis can also produce bullous, purpuric, lichenoid, papular, urticarial, pigmented, and hypopigmented reactions.

### MANAGEMENT

#### Uncomplicated Case

Treatment is similar for both irritant and allergic contact dermatitis. Topical steroids and emollients for milder disease and systemic medications including oral corticosteroids and antihistamines for more dramatic presentations are the basic treatments. Although the effectiveness of topical steroids has been well documented in allergic contact dermatitis, it is less well defined for irritant dermatitis. Elimination of the offending agent and liberal application of emollients are usually curative for mild irritant contact dermatitis, given that this form of treatment will speed resolution and decrease the chance of impetiginization resulting from scratching. Identifying the causative factors so they may be avoided is accomplished by good history taking by the physician. In chronic cases, a parent or older patient may need to keep a diary. More involved cases warrant a trial of topical steroids, given that the risks are minimal when they are used for a short time. In rare, severe cases of irritant dermatitis, just as with allergic contact dermatitis, systemic steroids are appropriate and can be given

for 2 weeks at a dose of 0.5 to 1.0 mg/kg with a rapid wean. A dermatologist may need to be consulted if the diagnosis is in question.

The treatment of diaper dermatitis requires gentle application of protective barrier ointments such as zinc oxide and petrolatum. Lowest-potency corticosteroids can be used in severe cases 2 to 3 times daily for a limited time (initially 3 days, and no longer than 2 weeks), and long-term exposure should be avoided in the occluded diaper area. Care of the diaper area includes bathing the child in water with minimal use of nondetergent soaps, followed by liberal use of emollients. Barrier ointments should be used with each diaper change with care not to produce excess friction. The involved areas should be kept dry and free of urine and stool, and caregivers should be encouraged to change the diaper frequently, as often as every 2 hours or more. Commercial cleansing wipes, if used, should be fragrance free and alcohol free. Topical antifungal agents work well for secondary candidal infection of the diaper area and should be considered in irritant rashes that are present for more than 3 days. Combination steroid-antifungal topical products should not be used in the diaper area.

With regard to the treatment of allergic contact dermatitis, Rhus dermatitis specifically, management includes washing the skin and other items that may have come in contact with the plant. Once the patient develops skin lesions, systemic antihistamines are usually needed. Topically, mild to moderate-strength (class 7 to 4) topical steroids are appropriate. In addition, topical pramoxine, an antihistamine, is safe and can be used over large areas of the body 2 to 3 times per day. If the lesions are limited but very pruritic, then a more potent topical steroid cream (class 1 or 2) can be applied for no more than 2 weeks. If the lesions are more extensive, then systemic steroids for 2 weeks at a beginning dose of 0.5 to 1.0 mg/kg followed by a rapid taper over the subsequent 2 weeks is justifiable. Dermatologists do not favor quick bursts of systemic steroids because they are often associated with rebound of the rash.

### Complicated Case

A suspected contact dermatitis that has not responded to treatment in a month, has involvement of a large body surface, or displays severe reactions (such as bullae) is a complicated case and may require skin biopsy. Patients who require patch testing (gold standard for identification of allergens causing allergic contact dermatitis) will require a referral to a dermatologist or pediatric allergist.

Patch testing involves the application of suspected allergens to intact, uninflamed skin. The substances of interest are usually applied to the back and are left on for 48 hours. After 48 hours, the patches are removed and the coded sites evaluated for the presence of a reaction, which can be erythema or bullae formation. Some positive reactions may not show for up to 7 days; thus, having the patient evaluated again at 5 and 7 days is useful. A commercially available patch testing system composed of 35 common allergens can be performed easily in the dermatologist's office. For more extensive patch testing, use of individually

prepared aluminum chambers with multiple allergens can be placed and then applied with hypoallergenic tape to the back. Of note, the technique of photopatch testing that detects contact photoallergy is also available. In this test, the patch is applied, and then after 24 hours the area is exposed to ultraviolet A light; the patch is read 48 hours later. Although data are limited, treatment of severe cases of contact dermatitis may involve topical or oral immunomodulators at the discretion of the dermatologist.

### PREVENTION

Irritant contact dermatitis can best be prevented by maintaining the skin barrier and by avoiding irritants. Parents and older children must be educated about common irritants including soaps and detergents, especially those with fragrance and dye additives. Formaldehyde, formaldehyde releasers, and other clothing treatments can aggravate the skin of children; clothing should be washed before wearing. Barrier function of the skin is preserved by maintaining a healthy stratum corneum. Skin should be well hydrated (but not overly hydrated) and well moisturized.

Allergic contact dermatitis is best prevented by identifying trigger factors and then educating the parent and older child about avoidance of triggers. Patients and their families should be taught to identify a poison ivy plant so that it can be avoided and removed, if possible. Commercial nickel spot tests are available from several sources. These user-friendly tests allow patients to detect the presence of nickel in metal items with which the patient may come in contact.

Finally, it is often simple and best for the patient if the entire family eliminates allergens. For example, the family of a patient sensitive to fragrances should all be practicing fragrance-free routines.

### WHEN TO REFER

- A child with presumed irritant contact dermatitis (including diaper dermatitis) that has persisted for a month or longer despite aggressive topical treatment should be referred to a dermatologist.
- A child with involvement of a large body surface area or displaying severe reactions (eg, bullae) or an atypical presentation may require referral to a dermatologist for a skin biopsy.
- Patients in need of patch testing should be referred to a dermatologist or qualified pediatric allergist.

### WHEN TO ADMIT

Generalized or systemic contact dermatitis as may occur from exposure to smoke of a burning antigen (ie, Rhus/Anacardiaceae family plant).

- Patient experiencing fever, chills, nausea, vomiting, or hypotension.
- Secondary bacterial infection requiring intravenous antibiotics.
- Secondary infection with a herpesvirus requiring intravenous antivirals.

## Chapter 236

# CONTAGIOUS EXANTHEMATOUS DISEASES

Dennis L. Murray, MD; Jennifer Vodzak, MD;  
Lilly Cheng Immergluck, MD, MS

*Exanthem*, meaning to bloom or to break out, refers to a skin eruption or rash that may be associated with fever. In children, the etiology is most often infectious, and may be caused by viruses, bacteria, parasites, or fungi; however, pediatric exanthems may also indicate noninfectious conditions, including rheumatologic, immunologic, and allergic diseases, as well as medication-related effects. These eruptions are extremely common in children and can present physicians with a major challenge in forming the differential diagnosis given the similarities in rash morphology and distribution among various illnesses. Careful exploration of the history and clinical manifestations other than rash is necessary to distinguish one disease from another. These factors include the incubation period, prodromal symptoms and signs, age of the patient, immunization history, contact or exposure history, distribution and progression of the rash, evidence of other organ involvement, and presence of pathognomonic signs (eg, Pastia lines or Koplik spots). Laboratory findings, including cultures and molecular testing, may be helpful in select cases and may assist in differentiating between infectious and noninfectious etiologies.

Some exanthems herald diseases for which treatment is necessary; others signal the need for specific isolation measures, reporting to public health departments, or perhaps further medical or epidemiologic evaluation. For example, certain infectious exposures pose risks to specific populations, such as a nonimmune pregnant woman exposed to rubella, or household contacts exposed to a patient with confirmed meningococcemia. Acute communicable diseases causing rash that respond to specific therapy

require special consideration. Recognition of the exanthem associated with *Neisseria meningitidis* infection (meningococcemia), for example, is essential for early and potentially lifesaving antibiotic treatment. Given the very different management strategies, careful differentiation between infectious exanthems and Kawasaki disease is important for appropriate treatment and monitoring (see Chapter 280, Kawasaki Disease). Additionally, it is important to differentiate between the exanthems of toxin-mediated streptococcal and staphylococcal disease, particularly in the era of increasing methicillin-resistant *Staphylococcus aureus* (MRSA).

Some of the differentiating characteristics of these and other eruptions are found in Chapter 186, Rash. This chapter focuses on exanthems associated with contagious viral and bacterial infections and does not discuss rashes associated with infections not transmitted person to person, such as Lyme disease (see Chapter 287).

## VIRAL EXANTHEMS

### Measles

Measles is one of the most serious of the childhood exanthems because of the morbidity and mortality associated with both the acute infection and the long-term permanent sequelae that can occur. The measles virus is highly contagious and is transmitted via respiratory droplets or by airborne transmission. The incubation period is typically 10 to 11 days. The prodromal illness is characterized by increasing fever, cough, conjunctivitis, and coryza. Fever commonly is high (104°F [40°C]) and, by day 4 of illness, the rash erupts. A deep erythematous macular rash begins on the face and neck and spreads down the trunk and extremities, similar to what occurs from a rubella infection. However, the rash on the face and upper portion of the trunk soon becomes confluent to produce the characteristic morbilliform rash, whereas the rash seen with rubella tends to remain discrete. The fever subsides and the rash begins to fade by day 6 of illness, leaving a faint brown pigmentation of the skin; a fine desquamation then ensues. With widespread use of measles vaccine, the differential diagnoses for a measles-like rash include Kawasaki disease along with a number of more common infections from enteroviruses, adenoviruses, and Epstein-Barr virus to bacteria such as *Mycoplasma pneumoniae* and streptococcal species.

The enanthem of measles is pathognomonic. Koplik spots, tiny bluish-white spots on an erythematous base that cluster adjacent to the upper molars on the buccal mucosa, begin approximately 2 days before the rash erupts and increase in number until day 1 or 2 of the exanthem. The combination of Koplik spots, fever, cough, conjunctivitis, and a morbilliform rash is sufficient to make a presumptive clinical diagnosis of measles. Although children are usually very ill, they recover rapidly by day 8 or 9 of illness and are often fully recovered by day 10 or 12; hence, the common term “10-day measles.”

Acute complications of measles are usually related to the inflammation that the virus induces throughout the respiratory tract, which can result in otitis media, bronchiolitis or laryngotracheobronchitis, and pneumonia. Otitis media is the most common complication, followed by pneumonia, which can be difficult to

distinguish clinically as to whether these symptoms are caused by measles virus or secondary bacterial infections. All children who have measles should have careful monitoring, and the examiner should have a high degree of suspicion for secondary bacterial infections of the upper and lower respiratory tracts. Rarely, other organ systems may be involved, including the central nervous system (CNS) with acute encephalitis (1 in 1,000 cases of measles). Vitamin A supplementation should be considered for immunodeficient patients and patients 6 months to 2 years of age who are hospitalized as a result of measles and its complications; limited data exist for Vitamin A use in the United States.

A rare but major complication of measles virus infection is subacute sclerosing panencephalitis (SSPE), also known as Dawson encephalitis. Disease occurs because of persistent measles virus infection in the CNS, with slowly progressive symptoms. Epidemiologic estimates of SSPE in the United States range from 4 to 11 cases of SSPE per 100,000 cases of measles, with increased risk if measles infection occurred prior to 2 years of age. Initially, SSPE produces headache, vomiting, drowsiness, and personality/behavioral changes, followed by progressive symptoms such as seizures and coma. In most cases, the cerebrospinal fluid (CSF) reveals pleocytosis and elevated protein levels with high CSF measles antibody titers. The prognosis is poor, with permanent neurologic sequelae and death commonly occurring within 1 to 3 years of diagnosis. Rare exceptions have been reported, with individuals showing remission or reversal of symptoms. Although numerous therapies have been attempted, none have proven to be efficacious or curative.

Endogenous measles transmission in the United States has been eliminated with the adoption of a routine 2-dose immunization schedule. Prevention of measles is discussed in Chapter 20, Immunizations.

### Atypical Measles

Atypical measles syndrome occurred in some children who were exposed to the wild-type measles virus and who had been previously immunized with inactivated measles vaccine used many decades ago (between the years 1963 and 1968). The constitutional symptoms and the distribution of the rash were similar to that of Rocky Mountain spotted fever. Elicitation of a history of having received killed measles vaccine assists in making the diagnosis. The inactivated measles vaccine is no longer available in the United States.

### Mumps

An exanthem will develop in fewer than 10% of persons infected with the mumps virus. When present, the lesions are maculopapular or morbilliform, pale pink, discrete, and concentrated on the trunk. The virus more typically involves the salivary glands, the testicles (after puberty), the pancreas, the kidney, and the meninges. After an incubation period of 16 to 18 days, clinical signs and symptoms develop in approximately 60% to 70% of infected persons. The remaining one-third of persons have inapparent or subclinical infections, without salivary gland swelling. Transmission is through direct contact with secretions from the respiratory tract.

The typical illness begins with 1 or 2 days of anorexia, headache, and mild to moderate fever. This period is followed by complaints of pain around the ear and discomfort when chewing. A diffuse but noticeable enlargement and tenderness of the parotid gland is present, often unilateral initially, then becoming bilateral in about 70% of cases. Occasionally, other salivary glands may be involved as well. Parotitis can be distinguished from lymph node enlargement in that it extends anterior to the ear and below the ramus of the mandible posteriorly to the mastoid bone, usually obliterating the angle of the jaw. Lymph nodes are more discrete and generally submandibular in location. Accompanying the parotitis, erythema is commonly seen around the opening of the Stensen duct. Differential diagnosis for parotitis includes other viruses (including human immunodeficiency virus, parainfluenza types 1 and 3, enteroviruses, and influenza), bacteria, and noninfectious causes such as parotid duct stones, tumor, and Sjögren syndrome.

CNS disease, manifested as meningitis or encephalitis, is estimated to occur in up to 10% of mumps cases and is characterized by headache, nausea, vomiting, and mild nuchal rigidity. It may occur before, during, or after the parotitis phase of the disease. CNS involvement follows a course similar to that of aseptic meningitis caused by other viruses, and it usually has no sequelae. In fewer than 2% of cases with CNS involvement, long-term neurologic sequelae or death occur. Cerebrospinal fluid pleocytosis has been noted in as many as 50% of mumps cases with parotitis, despite more than 90% of individuals with mumps showing no clinical evidence of meningeal irritation.

Orchitis is uncommon in children, but unilateral involvement of the testes and epididymis is observed in approximately 25% of male patients who are infected with mumps virus after puberty. Patients who have orchitis are usually quite ill; however, sterility rarely occurs. The pancreas and other exocrine glands are rarely involved. The kidney can be affected and result in a nephritis.

Prevention is achieved through immunization, with a current 2-dose recommended schedule. Unvaccinated or undervaccinated persons represent many cases of mumps occurring in the United States and worldwide, although more recent investigations have noted waning immunity to be a major contributor during outbreaks.

### Rubella

Rubella, also known as “German measles” or “3-day measles,” is caused by infection with rubella virus. These names served to distinguish the disease from rubeola (“hard measles” or “10-day measles”). Rubella was initially described as a clinical syndrome in the early 1800s by German physicians; however, it was not until 1962 that the virus was first isolated in tissue culture. The clinical spectrum of disease was documented more thoroughly during a United States epidemic in the mid-1960s that included more than 20,000 documented cases of congenital rubella syndrome. Transmission is through direct or droplet contact from respiratory secretions. The incubation period is 2 to 3 weeks, with a peak at 16 to 18 days. The period of

maximal communicability is 1 to 2 days before and up to a week after onset of the rash.

The typical clinical illness is mild and brief. In most children, the rash itself is the first sign of infection. It is typically a pink, maculopapular eruption beginning on the face and spreading downward to involve the trunk and extremities. The lesions remain discrete and pink, which contrasts with the raised, confluent, and deeply erythematous macular papules seen with rubeola. The facial rash clears as the extremity rash begins, and complete resolution of the entire exanthem occurs by day 3 to 5 of illness.

Fever is very mild (99°–101°F [37.2°–38.3°C]). Lymphadenopathy (usually posterior auricular and suboccipital lymph nodes) is frequently impressive. The affected nodes are usually tender at the onset of the rash, but the tenderness resolves rapidly over 2 to 3 days. Although lymphadenopathy is an important sign of rubella infection, it is not specific. An erythematous enanthem of pinpoint lesions or petechiae (known as Forchheimer spots) may occur on the soft palate; these lesions are often indistinguishable from those seen with scarlet fever or rubeola. The rubella virus is present in the pharynx within 5 days of the onset of the rash, but is difficult to culture. Serologic diagnosis is made by demonstrating an antibody titer rise between acute and convalescent sera taken 2 to 3 weeks apart.

Complications of rubella are rare in younger children. Arthralgias and arthritis can develop in approximately 15% of adolescents and young adults and can last up to a month, but the arthritis rarely becomes chronic. The most serious complications of rubella virus are usually related to congenital infections. If a susceptible pregnant woman is infected during the first trimester of pregnancy, there is a high probability that the fetus will become infected, causing multi-organ dysfunction or fetal demise. Since the introduction of the rubella vaccine in 1969, successful childhood vaccination efforts have decreased rubella infections from a high of 12.5 million in 1964 to fewer than 10 reported cases a year in the last decade, and have nearly eliminated congenital rubella syndrome cases in the United States. See Chapter 80, Perinatal Preventive Care: Fetal Assessment, for details on congenital rubella syndrome.

### Exanthem Subitum (Roseola)

Human herpesvirus-6 (HHV-6) is the infectious agent of roseola, also known as exanthem subitum (“sudden rash”) or roseola infantum (“rose rash of infants”). Transmission occurs via secretions containing the virus, most likely from an asymptomatic contact. Roseola is characterized by 3 or 4 days of high fever (104°–105°F [40°–40.6°C]), followed by abrupt resolution of the fever and development of a pink maculopapular rash that begins on the neck, sparing the face, and then spreads to the trunk and extremities. The lesions are discrete and last only for 1 or 2 days. While a seizure may occur in a small number of infants and children during the febrile phase, the child usually has no other manifestation of illness and does not seem as ill as the severity of the fever might imply.

Roseola occurs year-round and is generally limited to children between the ages of 6 months and

3 years. However, HHV-6 infections can cause a wide disease spectrum in persons of all ages, from asymptomatic shedding to encephalitis and seizures. See Chapter 267, Human Herpesvirus-6 and Human Herpesvirus-7 Infections, for a more complete discussion of these viruses.

### Erythema Infectiosum

Erythema infectiosum, or “fifth disease,” is caused by infection with parvovirus B19. Susceptible persons are infected by contact with respiratory droplets. The incubation period ranges from 4 to 14 days.

The typical clinical presentation is one of rash without fever or other systemic signs, though fever can occur in 15% to 30% of patients. The rash first presents as bright erythema of the cheeks and forehead with circumoral pallor, 7 to 10 days after nonspecific symptoms of malaise, myalgias, and headache. This “slapped-cheek” appearance is the result of many large macules and papules coalescing to form a confluent bright erythematous rash. These confluent areas are palpable and hot to the touch, but nontender. After a single day of facial rash, a maculopapular exanthem next appears on the proximal extremities, and can vary from faint to an intense erythematous exanthem. The rash spreads gradually to the trunk and distal extremities, leaving a reticular or “lace-like” appearance as it clears. This second stage lasts 2 to 4 days. In a third stage, the same rash may reappear transiently when the skin is exposed to pressure, sunlight, or temperature extremes of hot and cold. The rash usually resolves without any desquamation or pigmentation of the involved area. Arthritis and arthralgia, which often occur with infection in adults, are uncommon findings in children. The exanthem and arthritis are likely caused by immune complex deposition in the skin and joints.

Parvovirus B19 is an erythrovirus that, as the name suggests, has a predilection for infecting erythrocytes. Mild myelosuppression can occur, but typically goes unnoticed in healthy individuals, whereas a life-threatening red cell aplasia may occur in patients with shortened erythrocyte survival, such as those with hemoglobinopathies (eg, sickle cell disease or hereditary spherocytosis). This dramatic manifestation is primarily caused by the virus infecting erythroid precursor cells in the bone marrow, which results in premature red cell lysis.

Clinical suspicion may be confirmed, when necessary, by testing for anti-parvovirus B19 immunoglobulin M (IgM) in the immunocompetent patient or, in the case of the immunodeficient patient, by polymerase chain reaction (PCR) on blood/plasma. Those with aplastic crises may require transfusion. In immunodeficient patients with chronic infection, intravenous immunoglobulin (IVIG) therapy should be considered.

### Enteroviral Exanthems

With the widespread administration of effective rubeola (measles) and rubella vaccines, enteroviral infections have now become one of the most common causes of viral exanthems in children in the United States. Given the multitude of enteroviral serotypes, clinical manifestations may take a wide variety of

forms. Associated rashes may be macular, papular, pustular, morbilliform, petechial, urticarial, ulcerative, or vesicular, thus making diagnosis challenging. Many echovirus and coxsackievirus serotypes are, for example, associated with generalized maculopapular rashes that have discrete lesions similar to those of rubella. Other enteroviral exanthems may mimic a typical roseola infection, with an initial 2 to 3 days of fever followed by the rash. However, the enteroviral fever prodrome is usually much lower than that seen with roseola. Although maculopapular rashes predominate with enteroviral infections, vesicular lesions have been observed with certain enteroviruses, including coxsackievirus A5, A6, and A16, as well as echovirus 6. The clinical syndrome known as “hand-foot-mouth disease” is commonly caused by coxsackievirus A16 infection and is exhibited by small erythematous macules that evolve into small vesicles on the palms and soles and are often associated with discrete ulcers in the mouth (primarily involving the gums, tongue, and inner cheek areas).

Enteroviral exanthems typically occur in the late summer and early fall in temperate climates, and transmission occurs via the fecal-oral route. A number of enteroviruses are associated with epidemics of aseptic meningitis. A more detailed discussion of enteroviral infections and aseptic meningitis can be found in Chapter 248, Enterovirus and Evolving Infections, and Chapter 289, Meningitis.

### Infectious Mononucleosis

The exanthem associated with Epstein-Barr viral infections occurs in approximately 15% of children. The lesions are discrete, pink to red macules, or are maculopapular and have no specific distinguishing characteristic; therefore, the disease is most often diagnosed based on other signs of infectious mononucleosis and confirmed by the peripheral blood smear and serologic tests. The administration of ampicillin to persons who have infectious mononucleosis results in approximately 50% of them developing a much more intense rash, which may also occur with other penicillins. The ampicillin-associated rash is deeply erythematous and confluent, giving it a morbilliform appearance. This iatrogenic exanthem resolves spontaneously within a week after discontinuing the antibiotic. Appearance of such a rash in a patient treated for presumptive group A streptococcal pharyngitis is cause to reconsider the diagnosis. The physician should reassure parents that this rash does not represent penicillin hypersensitivity. The full spectrum of Epstein-Barr viral infection is discussed in Chapter 275, Infectious Mononucleosis and Other Epstein-Barr Viral Infections.

### Varicella Zoster Virus

#### Primary Infection (Chickenpox)

Varicella zoster virus (VZV) causes primary and reactivation vesicular exanthems. Recent advancement with widespread immunization in the United States has led to a large decline in wild-type varicella infections, commonly known as “chickenpox.” In this post-varicella vaccine era, the lesions of VZV infection in partially immune children may seem quite different than those of classic chickenpox seen routinely prior

to vaccine introduction. These more mild symptoms may include very few lesions that do not follow the typical pattern (as described in the following text). Physicians must have high suspicion to consider VZV resulting from this more atypical presentation. The exanthem of varicella infection (in either early classic or mild atypical form) can be readily confused with noninfectious conditions such as insect bites, allergic dermatitis, and drug reactions, as well as infections with enteroviruses or *S aureus*.

Nonimmune individuals with primary VZV infection typically develop classic chickenpox. The incubation period of the virus is lengthy, ranging from 10 to 21 days, with symptoms starting around day 14. Many children have a 24- to 48-hour prodrome of mild, nonspecific symptoms prior to rash eruption. The virus is initially spread via respiratory droplets, then additionally via secretions from the vesicular lesions once they erupt.

The chickenpox rash begins as erythematous macules that develop into vesicles containing clear fluid, classically described as the “dew drop on a rose petal.” The rash is often intensely pruritic. Within 2 days, the fluid begins to cloud and the lesions scab or crust. The initial lesions form on the scalp, the face, and occasionally the trunk. As these lesions begin to resolve, new vesicles erupt in stages over the trunk and extremities. This pattern continues for 1 to 7 days in otherwise healthy children. The number of lesions usually does not exceed 300, but children can develop more than 2,000 lesions in more severe cases. The lesions self-resolve slowly over 1 to 2 weeks. Fluid from the open vesicles contains live virus, thus transmissibility is decreased as the lesions dry and form scabs. Acyclovir may be used in certain groups to shorten the disease course and limit eruption of new vesicles.

Complications of varicella infection in immunocompetent persons can include most common secondary bacterial infections, as well as less common virus-related complications such as encephalitis, hepatitis, thrombocytopenia with hemorrhage, and, rarely, nephritis or arthritis. Given the pruritic nature of the rash, scratching can cause extensive excoriations, further increasing the risk of secondary bacterial skin infections. Usual bacteria include *S pyogenes* and *S aureus*, both of which can lead to a spectrum of concomitant disease from impetigo and cellulitis to invasive soft tissue infections to toxin-mediated disease and life-threatening sepsis. Immunocompromised hosts, including neonates and young infants, may exhibit more extensive and progressive disease with VZV infection.

Of note, 1% to 4% of healthy children who receive varicella vaccine may develop a mild, brief, atypical chickenpox rash (usually only a few lesions) within 1 to 2 weeks after vaccination. In these cases, the child is considered contagious, particularly if in contact with immunocompromised persons, until the lesions are crusted or resolved. See Chapter 227, Chickenpox, for full discussion of VZV infections and management.

#### Reactivation (Herpes Zoster)

Reactivation of VZV, known as “herpes zoster,” can occur in both healthy and immunocompromised persons. Herpes zoster manifests as a localized vesicular

exanthem in a dermatome pattern, related to the sensory nerve distribution containing the latent virus. The initial lesions resemble those of primary VZV infection, but progress into larger, coalesced areas and are usually associated with neuralgia and hyperesthesia in addition to pruritis. New lesions can continue to appear for up to 1 week, followed by crusting of lesions and slow resolution over an additional 2 weeks. The most common complication is post-herpetic neuralgia, which occurs more often in adolescents and adults. Secondary bacterial infections can also occur, as with primary VZV infection. Antivirals may be indicated for certain patient populations.

See Chapter 227, Chickenpox, for full discussion of herpes zoster presentations and management.

### Herpes Simplex Virus

Herpes simplex virus (HSV) causes both vesicular exanthems and enanthems, with wide clinical variation based on age, affected body site, primary infection versus reactivation, mode of acquisition, and host immune status. Many HSV infections or reactivations (with either HSV-1 or HSV-2) are asymptomatic. If lesions are apparent, they can be either mucosal or cutaneous, and may affect a number of different body sites.

Mucosal manifestations can include lesions of the mouth, pharynx, lips (vermillion or mucocutaneous border), eye (conjunctiva), female genital tract (vagina and adjacent structures, cervix), and male genital tract (urethra). These lesions can be vesicular or ulcerative, are usually painful, and may be associated with nonspecific constitutional symptoms. In young children, primary herpes gingivostomatitis is usually caused by HSV-1 and presents as extensive, painful vesicles of the oral mucosa and palate, with extension to the lip, tongue, and face. In older children and adults, pharyngitis may represent primary HSV infection and can be difficult to distinguish from other, more common causes of pharyngeal edema and erythema, such as Group A streptococci or Epstein-Barr virus. Orolabial HSV lesions (reactivation HSV) are quite common in the general population, and are usually seen as single or grouped, tender, vesicular lesions on an erythematous base at the vermillion border, often preceded by paresthesias. Ocular herpes infections, or keratoconjunctivitis, can be severe and cause permanent corneal scarring with potential vision loss, although milder forms can occur.

Cutaneous manifestations of HSV infections can take a wide variety of forms. Vesicular lesions are observed most often over skin near affected mucosal surfaces, such as the perioral and genital areas. However, lesions can develop on any area of skin, and cutaneous eruptions have been associated with transmission of HSV during certain contact sports, such as wrestling and rugby (known as *herpes gladiatorum* or *mat pox* and *herpes rugbiorum* or *scrum pox*, respectively). HSV can also cause infection within an already disrupted skin barrier, as in *eczema herpeticum*. Additionally, cutaneous HSV infections can present as infection of the pulp or nail bed of a finger or toe, known commonly as “herpetic whitlow.” Infection can initially resemble a bacterial cellulitis, but usually follows vesicular or pustular lesions on the affected digit. The symptoms are not responsive to antibiotics and

usually progress to a purple to gray discoloration of the digit. Finally, a less common cutaneous presentation associated with HSV is the nonvesicular exanthem of erythema multiforme (EM), especially in recurrent EM cases.

In immunocompromised persons, including neonates, HSV disease can be life threatening. For these patients, HSV exanthems or enanthems seem similar; however, disease may be more severe, more difficult to control (increased frequency of reactivation), or more likely to disseminate. Mucocutaneous lesions are part of the spectrum of neonatal HSV disease known as “skin, eye, and mucus membrane disease.” These lesions may occur with or without more serious, life-threatening invasion (dissemination or CNS involvement). The lesions are vesicular, and virus can be isolated from specimens of the conjunctiva, oral mucosa, rectum, and skin lesions.

Nonexanthematous manifestations of HSV infection can occur, including encephalitis, hepatitis, esophagitis, pneumonitis, and other disseminated forms. For a full discussion on infections caused by HSV and corresponding management, see Chapter 266, Herpes Infections.

### Molluscum Contagiosum

This benign, usually asymptomatic skin infection is common in infants and children and is caused by a poxvirus. Adolescents and adults can also acquire the infection through sexual activity and certain types of sports (eg, wrestling). Humans are the only known source of the virus. Typical lesions are discrete papules, 1 mm to 6 mm in diameter, that can be skin-colored, erythematous, or translucent (and mimic a vesicle) and are sometimes umbilicated. The rash can occur in any cutaneous location but is more common on the face, eyelids, neck, chest, axillae, folds of the extremities, and genital region. Lesions may be linear because of autoinoculation, and there may be an associated dermatitis in the area of the papules in 10% of patients. The diagnosis is typically made clinically; however, scraping a characteristic papule and staining the materials with Giemsa or methylene blue reveals a molluscum (Henderson-Patterson) body with direct microscopy.

Molluscum contagiosum lesions may resolve spontaneously over an extended period of time (months), and watchful waiting is an acceptable management plan. However, many parents will request treatment, and therapy may be warranted to alleviate discomfort, reduce autoinoculation, and limit transmission to close contacts. Options for therapy include either curettage or cryotherapy with liquid nitrogen of the individual lesions. Both of these therapies are effective but may be traumatic for young children; curettage may also cause spread of lesions and scarring. Application of cantharidin (blister beetle extract) or imiquimod cream are both off-label options. Imiquimod cream is applied 3 times per day, and contact dermatitis can be a problem with this therapy. Facial lesions, in particular, can be treated with topical retinoids (eg, tretinoin), but because this therapy’s mechanism of action is induction of irritant dermatitis, this type of treatment may also have limiting side effects.

Severe disease in immunocompromised individuals can be treated with intravenous cidofovir, however, this agent is associated with known toxicities, including renal failure.

When the diagnosis is uncertain, if extensive disease is present, or if the condition is associated with poorly controlled atopic dermatitis, referral to dermatology or infectious disease specialists should be considered.

## BACTERIAL CONTAGIOSUM

### Meningococcemia

One of the most serious, contagious exanthematous diseases in adults and children is caused by *Neisseria meningitidis*. Roughly two-thirds of patients with meningococcemia will develop cutaneous manifestations. Transmission of the organism occurs via respiratory droplets or direct/indirect oral contact, with an incubation period of 1 to 10 days.

Symptoms of meningococcemia, at the onset, may mimic those associated with a viral illness (fever, myalgia, headache, nonspecific constitutional symptoms). Initially, erythematous, urticarial, or morbilliform macules and papules may appear, and petechiae, pustules, and vesicles may also develop. The hallmark manifestations of the disease, and the most disturbing features, are purpuric lesions with jagged edges. These lesions may progress to necrosis, ulcers, and eschars. Profound hypotension and shock occur with overwhelming meningococcemia. Purpura fulminans, purpuric and necrotic plaques combined with disseminated intravascular coagulation, is associated with significant mortality (invasive meningococcemia mortality is 8%–10%) and morbidity (loss of limbs, digits, or other body parts).

Physicians need to be knowledgeable about the presenting signs and symptoms as well as the treatment of meningococcemia. Cultures of the blood and cerebrospinal fluid (CSF) are confirmatory. Supportive management including fluids and vasoactive agents, usually within a critical care setting, is often required. Treatment with an empiric antibiotic, such as ceftriaxone, is required to provide adequate coverage of the CNS as well as a variety of bacteria capable of causing sepsis. Once the cause of the patient's illness is confirmed to be *N meningitidis*, definitive treatment is recommended. (See Chapter 289, Meningitis.) Five to 7 days of intravenous antibiotics should be given. Close contacts within 7 days prior to patients presenting with invasive meningococcal disease are at high risk and should receive antibiotic prophylaxis, ideally within 24 hours after the index patient has been identified.

Effective vaccines exist for 4 of the 5 serogroups of *N meningitidis* that are responsible for most cases of meningococcemia (A,C,Y,W-135), including meningococcal conjugate vaccines for use in persons 9 months through 55 years of age. Routine recommendation for use of meningococcal vaccine exists for all adolescents 11 to 12 years of age with a second dose at 16 to 18 years of age; additional recommendations for immunocompromised and high-risk populations have recently been forthcoming. As of 2015, 2 serogroup B meningococcal (MenB) vaccines have been approved by the US Food and Drug Administration for use in

persons 10 to 25 years of age. The US Centers for Disease Control and Prevention (CDC) recommends routine vaccination against serogroup B meningococcal disease for people aged 10 years and older who are at increased risk of disease, including those with persistent complement component deficiencies, with anatomic or functional asplenia, or at increased risk because of a disease outbreak. Further, the CDC Advisory Committee on Immunization Practices recently added the recommendation that a MenB vaccine series may be administered to adolescents and young adults aged 16 to 23 years to provide short-term protection against most strains of serogroup B meningococcal disease (preferred age is 16–18 years).

All confirmed, presumptive, and probable cases of invasive meningococcal disease should be reported to the appropriate health department.

### *Mycoplasma pneumoniae*

Cutaneous signs are a minor manifestation of *Mycoplasma pneumoniae* (*M pneumoniae*) infections. A maculopapular eruption may appear on the trunk and extremities of 10% to 15% of persons infected with *M pneumoniae*. Even more commonly associated with *M pneumoniae* infection are the rashes that result from an immune-mediated or allergic response. The spectrum of these rashes is broad, and includes urticaria, erythema multiforme, and vesicles or bullae. Such patients often have had a prodromal illness of fever, headache, malaise, and cough. Pneumonia may be subclinical, with chest radiographic findings out of proportion to what is found on clinical presentation or examination. Macrolide antibiotics, doxycycline for those 8 years or older, and levofloxacin for older adolescents and adults may be used to treat *M pneumoniae* infections. (See Chapter 315, Pneumonia.)

### Scarlet Fever (*Streptococcus pyogenes*)

Scarlet fever is a clinical syndrome of fever, pharyngitis, and rash often with associated nausea, abdominal pain, and headache. The rash of scarlet fever is caused by an erythrogenic exotoxin produced by some strains of Group A  $\beta$ -hemolytic streptococci (GABHS or *S pyogenes*). This rash is characterized by a fine papular eruption on a brightly erythematous macular base. The papular rash is typically concentrated on the trunk and proximal extremities and has been likened to "fine sandpaper." Transverse erythematous streaks of coalesced petechiae (Pastia lines) are sometimes present, usually in the antecubital spaces. In addition, the rash is commonly associated with prominent erythema of the lips, soles, and palms along with circumoral pallor. The examination of the tongue may reveal prominent papillae on a very erythematous base, giving a "strawberry tongue" appearance. During the recovery phase, desquamation typically occurs and can resemble the peeling associated with mild sunburns; desquamation may be more prominent at the fingertips and along the palms and soles.

It is important to distinguish streptococcal infections causing rash from staphylococcal infections causing similar dermatologic manifestations. *S aureus* produces a wide range of toxins, including an

exfoliative toxin that may cause a scarlet fever–like rash with erythroderma and desquamation. Attempting to distinguish these 2 clinical entities is important to choose appropriate antibiotic therapy, particularly in light of the increasing prevalence of community-associated methicillin-resistant *S aureus* (CA-MRSA).

Streptococcal infections are treated with penicillin or erythromycin, whereas methicillin-susceptible *S aureus* (MSSA) infections can be treated with first-generation cephalosporins (cephalexin), penicillinase resistant penicillins (dicloxacillin, oxacillin, nafcillin), or clindamycin (if susceptible). Because of the high incidence of skin and soft tissue infections caused by CA-MRSA in the United States, either trimethoprim-sulfamethoxazole (TMP-SMX) or clindamycin is often selected to empirically treat these focal infections when CA-MRSA is suspected. However, caution is advised when choosing TMP-SMX if the causative pathogen could be GABHS, since this antibiotic will not eradicate that organism. When possible, cultures from the focal infection site should be obtained to guide antibiotic therapy options.

Kawasaki disease must be carefully differentiated from scarlet fever, because coronary artery disease may be a complication that requires distinct therapy in a significant percentage of children with Kawasaki disease. The cutaneous manifestations overlap remarkably with those of scarlet fever, but it can usually be distinguished by the additional signs of discrete bulbar conjunctivitis without exudate, cracking of the lips, tender lymphadenopathy (usually solitary, unilateral, and more than 1.5 cm in diameter), meatitis, diarrhea, and changes in the extremities including induration/edema with erythema of palms and soles. These children are profoundly irritable, and their fever persists beyond 5 days in most cases (diagnostic criterion). Just as in scarlet fever, however, patients usually have erythema of the palms and soles, erythematous lips, and a strawberry tongue, with striking desquamation during the second and third weeks of the illness; the desquamation with Kawasaki disease typically involves the periungual areas and groin. Kawasaki disease is presented in more detail in Chapter 280.

### **Staphylococcus aureus**

Beginning in the early 1990s, infections caused by *S aureus* increased dramatically, and the most common manifestation involved the skin and soft tissues. Specifically, this increase in *S aureus* infections has been attributed to CA-MRSA. The differential diagnoses associated with *S aureus* skin infections, and specifically, CA-MRSA skin infections, include *S pyogenes* infections. Transmission is presumed to be by close contact with infected or colonized skin or contaminated fomites (eg, towels, razors). Common skin manifestations of CA-MRSA infections include impetigo, ecthyma, and folliculitis; these infections are limited to the epidermal layer of the skin or in the case of folliculitis, the hair follicles within this layer. Although erysipelas is usually caused by *S pyogenes*, in the era of CA-MRSA infections, staphylococci must also be considered as a causative pathogen. With erysipelas, the skin appears erythematous and warm with

some edema; usually, there are also associated systemic symptoms including fever and chills. The superficial dermis and lymphatic channels are often involved. Cellulitis, now most commonly caused by *S aureus* and not *S pyogenes*, usually presents as erythema with some degree of purulence and involves the epidermis, dermis, and subcutaneous fat layers of the skin. Superficial skin abscesses are by far the most common CA-MRSA-related skin infection. These abscesses usually involve suppurative collection of fluid or pus in the cutaneous and epidermal layers of the skin and often coexist with cellulitis. Furuncles (commonly referred to as “boils”) and carbuncles (coalescence of multiple furuncles) are suppurative in nature and often extend beyond the epidermal layer to involve the dermis or subcutaneous tissue.

For suspected CA-MRSA skin infections, use of clindamycin, TMP-SMX, or doxycycline is typically recommended. Over the last decade, increasing rates of clindamycin resistance among CA-MRSA isolates have been demonstrated, so empiric antibiotic treatment should be based on local or regional antibiograms for MRSA isolates. Additionally, the D-test is recommended for detection of inducible clindamycin resistance in erythromycin-resistant, clindamycin-susceptible isolates. For purulent cellulitis, where there is purulent drainage or exudate in the absence of a drainable abscess, empiric therapy is also recommended pending culture results. In some cases of small abscesses (<5 cm) without evidence of systemic symptoms, incision and drainage alone without antibiotics may be sufficient for treatment; this is usually not recommended if infection involves an infant or young child or if the infection is spreading quickly or involves multiple lesions.

For a complete discussion of *S aureus* infections and toxin-mediated syndromes, see Chapter 340, Toxic Shock Syndrome.

## Chapter 237

CONVERSION REACTIONS  
AND HYSTERIA

Gregory E. Prazar, MD

DEFINITION, INCIDENCE,  
AND ETIOLOGY

The amalgamation of emotions and physical symptoms in patients challenges the primary care physician to formulate priorities in history taking, diagnosis, and management. Some somatic complaints, such as headaches, nausea, and vomiting, can result directly from emotional upsets. Indeed, anxiety is often associated with palpitations, sweating, and tremulousness; depression is often exhibited by symptoms of fatigue and weakness. Other somatic complaints reflect organic disorders, such as neuromuscular headaches, which may be associated with emotional turmoil. Still other physical problems are attributed to conversion symptoms. The terms *conversion symptom*, *conversion reaction*, and *conversion disorder* are often used interchangeably. Somatic or functional complaints differ from conversion symptoms in that patients with somatic or functional complaints are aware of emotional distress associated with the symptom. Patients with conversion symptoms are not cognizant of any associated emotional distress.

Conversion reactions are a way of communicating the uncomfortable, or as Engel writes,

... a psychic mechanism whereby an idea, fantasy, or wish is expressed in bodily rather than in verbal terms and is experienced by the patient as a physical symptom rather than as a mental symptom.

The idea or wish is psychologically threatening to individuals or is unacceptable for them to express directly. A conversion symptom serves as a form of decompression whereby unpleasant feelings associated with acknowledgment of the wish are dissipated through the use of a somatic symptom. Because the wish is completely unconscious, patients in no way relate any psychologic stigmata to the somatic complaint. As Hollender succinctly states, "The conversion symptom is a code that conceals the message from the sender as well as from the receiver."

To understand why a wish or thought is represented by a bodily symptom, exploring patterns of everyday behavior and infant development is necessary. Body activity (ie, gesturing) is used to express ideas during verbal interaction. Common conversational phrases often allude, metaphorically, to the intermixing of emotion and body functioning. "I'm fed up" and "He is a pain in the neck" are 2 such examples. Developmentally, infants express feelings and communicate through visible behavior long before spoken language becomes their dominant mode of communication. Furthermore, infants explore and learn about their environment, including the people in it, by using their bodies as investigative tools (eg, placing new objects in the mouth) and as a means of

making contact. Any bodily process that can be perceived by the individual can serve as the focus for conversion symptoms. Similarly, somatic symptoms of relatives or close friends also can serve as the source of a patient's complaints. The patient's interpretation of the other person's symptom provides a model for the somatic complaint. When the symptom is adapted from one observed in the other person, that person often evokes strong feelings in the patient. Because the patient expresses guilt about feelings or impulses toward that person, the patient may take the other person's symptoms as a form of self-punishment while at the same time psychologically expressing the forbidden idea or wish.

All body systems may be invoked in a conversion reaction. The sensory system frequently is involved (eg, paresthesia, anesthesia, or diffuse pain), although typically these symptoms are not distributed in the correct pattern of innervation of the implicated cutaneous nerves. Motor system involvement can be represented by paralysis, tremors, or weakness of an extremity. Hyperventilation and dizziness are other common conversion symptoms, as are nausea and vomiting and visual problems.

A common conversion symptom seen in children and young adolescents is abdominal pain. After an extensive investigation of 100 children who had abdominal pain, Apley found an organic cause in only 8 cases. Another study by Oster revealed abdominal pain in 14% of the children studied. The incidence was highest in individuals 9 years of age and lowest in those 16 to 17 years of age. Recurrent abdominal pain and its causes remain controversial (see Chapter 125, Abdominal Pain). However, an important point to remember is that many patients who have recurrent abdominal pain may have emotional concerns of which they are unaware. Many of these patients may be experiencing conversion symptoms.

Although the incidence of certain individual somatic complaints has been studied, the specific overall incidence of conversion symptoms in children and adolescents is not known. Available data suggest an incidence of 5% to 13%. Lack of more definitive data reflects the difficulty in ascertaining whether a somatic complaint indeed represents a conversion symptom. Conversion symptoms may seem to be more common among adolescents than among younger children because the former more often have alarming somatic complaints, such as chest pains and fainting spells, whereas younger children frequently suffer from more indolent complaints, such as sporadic abdominal pains. Conversion symptoms are 2 to 3 times more common in girls than in boys and may appear as early as 7 or 8 years of age. No correlation seems to exist between the occurrence of conversion symptoms and socioeconomic status; however, patients with less sophisticated understanding of medical issues tend to have rare or very unusual and physiologically unexplained symptoms. Therefore, the more classic conversion symptoms (eg, paralysis or blindness) are less likely to be seen by physicians in Western societies. These physicians are more likely to diagnose conversion symptoms in patients presenting with chronic abdominal pain or chronic headaches.

Conversion symptoms can appear as a group phenomenon. Such a situation is often referred to as *epidemic hysteria*. Adolescent girls swooning and fainting at rock concerts is an easily appreciated example. In this situation, the unacceptable wish relates to sexualized thoughts involving rock stars. Other examples of epidemic hysteria are explained less easily. Episodes of epidemic hysteria seem to have several characteristics in common—audiovisual cues (eg, seeing ambulances arrive to care for accident victims) seem to be important as precipitators; girls are involved more often than boys; the reaction is more likely if it is initiated by a group member identified either as a leader (of a large subgroup) or as an outsider; and episodes are likely to involve larger numbers of adolescents if the youngsters are allowed to confer among themselves without adults present. Entire school populations may be involved in mass conversion reactions.

Although conversion symptoms have no organic basis by themselves, their perpetuation may result in biochemical or physiologic body changes, known as conversion complications. These events can include changes such as muscle atrophy caused by long-standing paralysis and respiratory alkalosis secondary to acute hyperventilation.

## INTERVIEW TECHNIQUES

Because symptoms caused by conversion and somatic processes can be easily confused, the physician evaluating any youth who has a somatic complaint should always consider the possibility of a conversion symptom. Attention to personal history (family functioning, school performance, and peer relationships) and to physical functioning demonstrates to the youth and family that the physician appreciates without prejudice the importance of all elements that may be contributing to ill health. Showing respect for the importance of emotional-physical interaction is thereby suggested so that this concept will not be foreign if it is later presented to the family in a diagnostic framework. Such an approach also contributes to the physician's understanding, as Engel states, "of those personal, family, and social circumstances that are most relevant to the understanding of the illness and the care of the patient, whether or not the ultimate diagnosis is conversion."

Nondirective interviewing proves more rewarding than direct questioning. For example, asking the patient to describe the pain ("Tell me how it feels.") almost always provides insight into the emotions that the patient associates with the symptom. Suggesting how the symptom feels to the patient ("Is it dull or sharp pain?") limits possible responses. If the patient spontaneously offers information about recent events, then the interviewer should obtain further data related to such changes in the youth's life. However, care should be taken to avoid suggesting a cause-and-effect relationship between the youth's feelings and the symptoms. Because people who have conversion symptoms have no conscious knowledge of such an association, the suggestion of such a relationship may alienate them and prevent the establishment of a trusting relationship.

## DIAGNOSTIC CRITERIA FOR CONVERSION SYMPTOMS

The conversion symptom has a specific, but unconscious, symbolic meaning to the patient. In other words, the conversion symptom is often related to an unconscious wish, and the physical impairment serves to prevent acting out the wish. For example, the adolescent boy who has hand paralysis may have anxieties about masturbating. The physician treating children and adolescents may not always be aware of the symbolic meaning of the symptom. Indeed, the concept that conversion symptoms have a symbolic meaning to the patient was formulated only after a series of these patients had undergone extensive psychotherapy. Although being cognizant of the presence of the symbolic meaning may be intellectually rewarding for the physician, ignorance of the specific symbolism does not prevent adequate treatment (Box 237-1).

Adolescents who have conversion symptoms often display characteristic patterns of behavior, sometimes designated as traits of the *hysterical personality*. Such characteristics include egocentricity; labile emotional states (quick shifts from sadness to elation and from anger to passivity); dramatic, attention-seeking behavior; and sexual provocativeness (displayed in gestures and in dress). Adolescents who have such characteristics are also usually demanding, display an air of pseudomaturity, and are dependent in personal interactions. Their personal relationships, however, are rarely intimate or satisfying. Although many aspects of the hysterical personality are seen in adolescent patients who have conversion symptoms, such characteristics are also demonstrable in adolescents who do not have such symptoms. Therefore, hysterical behavior traits in adolescents are not synonymous with conversion symptoms and, in isolation, are not indicative of a psychopathologic condition.

The manner in which patients who have a conversion symptom describe their problem is often distinctive. The account frequently is dramatic. A pain may be described as "thousands of burning needles thrust into my leg" or as "a giant spike being driven into my chest." Because these patients are suggestible, any symptom description alluded to by the physician may be adopted readily and thereafter reported, which again emphasizes the importance of a nondirective approach in the interview.

### BOX 237-1 Case Report

Jane, a 12-year-old, suddenly developed an inability to walk. Physical examination, including a neurologic evaluation, revealed no abnormalities. Interviews by a psychiatrist and a pediatrician working as a team revealed no apparent symbolic causative factor. The pediatrician formulated a system to reward Jane's progress in walking and implemented this approach; the psychiatrist was similarly supportive with the patient. Over a period of 3 weeks, the patient regained her ability to walk.

Conversion symptoms are adopted unconsciously in an attempt to reduce unpleasant feelings, especially anxiety, depression, and guilt. Therefore, although patients may describe incapacitating pain, they often affect an air of unconcern. Psychiatrists refer to this as *la belle indifference*. The extent to which the conversion symptom diminishes the unpleasant feeling and symbolically communicates the forbidden wish for the patient is referred to as the *primary gain*. Patients who have conversion reactions are often stubborn in their belief that the symptom is caused by organic problems, which reflects denial of the underlying emotional problem. Conversely, insistence (especially by an adolescent) that a symptom is psychologic in origin may indicate denial of a physical problem. Therefore, differentiating between conversion symptoms and physical disease in adolescent patients cannot depend solely on the youth's emotional response.

Conversion symptoms not only result in a primary gain for patients, but they also help them cope with the environment. In this respect, the conversion symptom achieves a secondary gain for patients. For example, patients who have a conversion symptom defending against homosexual thoughts may be excused from attending school, where anxiety may have been intensified (eg, in the locker room). Limitations imposed by the symptom may contradict patients' verbalized wishes to participate in activities but, nevertheless, remove them from potentially threatening social interactions. Interference with daily activities also provides a secondary gain in that attention and more frequent expressions of love are elicited from concerned parents and friends. This situation may be resistant to change, not only because the symptom is reinforced continually, but also because the symptom meets the parents' psychological needs. In effect, the symptom may provide the parents with a reason for inappropriately attending to or infantilizing their children. Consequently, patients and their entire families may fall into a vicious circle of dependence on the symptom.

Demonstration of a secondary gain does not ensure a diagnosis of conversion. To an extent, all illness is involved with some secondary gain. Bedridden patients must accept increased attention to cope with their physical confinement. Therefore, a degree of secondary gain is necessary for adequate adaptation to a physical disability. However, in the case of a conversion symptom, secondary gain not only intensifies symptoms but also may be associated with further occurrence of somatic complaints. Because perpetuation of secondary gain depends on concern from others, a conversion symptom is exhibited more readily in the presence of individuals meaningful to the patient.

Children and adolescents who develop conversion symptoms are often overprotected and become extremely dependent on their parents. Daily familial communication may have been invested heavily in somatic complaints, with children recognizing how often activities may have been canceled because of a father's headaches or a mother's cramps. Therefore, a child's symptoms may conform to the unspoken interactional rules of the family. Family members indirectly

reinforce patient problems, although the family may assume an air of indifference with respect to the symptoms (Box 237-2).

Precipitation of a conversion symptom may be related to specific stressful events. A change of school, final examinations, new social experiences, and parental conflict are examples of events that may induce a conversion symptom. Unresolved grief reactions may represent a source of stress that can precipitate a conversion symptom. Examples of grief reactions include death of a parent, divorce, or moving. Furthermore, adolescent and adult patients experience pseudoseizures more often in families in which an *unspeakable dilemma* is present. Specifically, the dilemma is often associated with a fear of physical or sexual assault. Even though other family members are aware of the specific dilemma, they often underestimate how severely the family member who experiences the pseudoseizures is affected by the dilemma. Because the patient's association between conflict and the conversion reaction is unconscious, a history is helpful only if the interviewer elicits details about daily activities. The stressful event precipitating a conversion symptom often becomes apparent only after many visits (Box 237-3).

#### BOX 237-2 Case Report

James was a 13-year-old who had severe abdominal pain and was referred to a pediatrician by his family physician. Physical examination revealed little objective evidence of abdominal pain in the physician's office. However, his return home quickly resulted in intensified pain. Abdominal pain seemed to be well controlled during a subsequent 4-day hospitalization (all organic tests were unremarkable). His return home again produced an immediate exacerbation of the abdominal discomfort. Furthermore, John, James' identical twin, began exhibiting signs of abdominal pain. The boys' mother admitted feeling trapped by the demands of her children and volunteered that, in the past, she had been treated for chronic abdominal pain. The appearance of abdominal pain in both twins reassured her that the pain was "probably a virus." She chose not to pursue further counseling for the boys.

#### BOX 237-3 Case Report

Chip, a 13-year-old, was brought by his mother to his pediatrician because of chronic abdominal pain, which seemed to be precipitated by his competing in horse-riding events. His history revealed the death of a grandparent 4 months previously, but his mother related that her son's pain preceded the onset of the fatal illness. Other family stresses were denied. The teenager did not appear for follow-up care but returned 6 months later, primarily because his mother wanted to discuss her son's reaction to her upcoming divorce. At this visit, the mother volunteered that marital stress had been ongoing for several years.

Symptom selection is based on the unconscious remembrance of the patient's own body function or understanding of symptoms in others. The patient's conversion symptom may seem quite dissimilar to that displayed by the other (often a parent or a close relative) because the patient's perception of disease governs the display of symptoms. Parents and relatives often misinform children and adolescents about diseases, fearing that the truth would be too frightening. However, such misinformation may actually potentiate the adolescent's fantasies and result in the development of a symptom quite different from that actually experienced by the individual serving as the model (Box 237-4).

The choice of a symptom may also be based on a physical illness the patient had experienced previously. Thus, patients who have a history of seizures may, after many years of adequate anticonvulsant control, have atypical and physiologically unexplainable seizures. Unfortunately, these patients often receive only a physiologic workup for seizures. Despite the atypical history, the physician assumes that the diagnosis rests *where the money is, or was*, in the past (Box 237-5).

Because the complaint expressed by the patient is based on a model symptom, a physical disease often

is mimicked. Close scrutiny of the symptom's history and description often reveals anatomic and physiologic discrepancies. The child or adolescent who has a stocking anesthesia—an anesthesia confined to a specific area of an extremity without any relationship to cutaneous nerve innervation—demonstrates an example of such symptom inaccuracy. It is based on the concept of the patient's own body rather than on anatomic principles.
